SPECIAL ARTICLES.

SANITARY ASPECTS OF THE PANAMA AND NICARAGUA CANALS.

BY GEORGE A. SOPER, PH.D.,
OF NEW YORK.

THE Isthmian Canal Commission, appointed June 19, 1899, to investigate the practicability and feasibility of various projects for constructing a ship canal across the Central American Isthmus, have submitted their report to the Congress of the United States. While the matter stands before the representatives of the people and a final choice between routes is still open, it is of interest to inquire from a disinterested standpoint into the conditions which make for and against health in the countries and along the routes which are under consideration.

Upon the question of liability to, or immunity from, disabling diseases rests the problem of labor, and all persons are agreed that the greatest difficulty to be encountered in the construction of the canal will be the procurement of an adequate supply of laborers and the preservation of their health and efficiency. In view of this fact it is rather curious that the exhaustive report of the Isthmian Canal Commission should not have discussed the question of health more thoroughly. In their report of 263 pages less than a page and a half is devoted to hygiene and in the 40 appendices which accompany the report there is no discussion of the subject presented.

Not only is the question of health a factor to be considered in the construction of the canal, but when the canal is completed the rôle of this great waterway in promoting or endangering public health will be a subject of immense commercial importance.

General Description of the American Isthmus.—The Central American Isthmus in the most extensive meaning is about 1,400 miles long and extends from the 77th to the 95th meridian of longitude and from the 8th to the 18th parallel of latitude. The 9th degree of latitude nearly bisects the route of the proposed Panama Canal, while the 11th parallel cuts that of Nicaragua. The general direction of the Isthmus is from southeast to northwest, the first 600 miles to the eastward being comparatively small in width. It varies from a minimum of barely 30 miles to a maximum of 120 miles. The land is of volcanic origin and consists of mountain ranges which unite the Andes on the south with the great chain of mountains which extend along the western border of the United States. Below the mountains are many plateaus, plains and small stretches of land, some of which are but slightly elevated above the level of the sea. The most available routes for a canal across the Isthmus are considered to be the Nicaragua and Panama lines, which would have a length of 183.66 miles and 49.09 miles respectively.

Most observers writing on the health conditions natural to the low lands of the Isthmus describe the region as unhealthy to the natives and peculiarly fatal to Europeans. Since the period of the Spanish conquest many attempts have been made to colonize Central America, but the foreigners of Spanish extraction are the only ones who have been able to withstand the climate with even a tolerable degree of success. The natives are described as inferior in the social scale, of a wan, sallow tint, with softness and puffiness of the tissues, poverty of the blood, extra large development of the stomach and with a tendency toward congestion of the liver and spleen. This is accompanied by a state of languor, dulness of the intelligence and of the entire nervous system. Near the sea and along the lines of the proposed Panama and Nicaragua Canals, much of the land is low and comparatively flat, with sluggish water courses and all the characteristics of a tropical vegetation. Putrid emanations from decomposing organic matters prevail everywhere and their deleterious effects, considered not as agencies of specific diseases but more particularly as unwholesome gases, are evident.

The physiological effects often observed in the tropics prevail on the Isthmus. The large amount of moisture which prevails in the air lessens evaporation from the skin and lungs, and this condition, with the continuous heat, shows its effects in loss of appetite, depression of spirits and in disorders of the kidneys, stomach and intestines. In new arrivals the body-heat may reach an excess of 1° F. above normal and frequently exceeds the temperature of the outside air. As a rule, however, the atmosphere is much warmer. This causes the metabolic processes which in northern climates turn a part of the food materials into heat to be reversed, and the vital functions are then called upon to neutralize the excess of heat received in order to maintain the body at a normal temperature. This throws additional work upon the excretory organs which, under other conditions, would be concerned in throwing off only a portion of the products of the food absorbed. The excess of work and alteration of functions described are important predisposing causes of disease as are the following physiological effects of hot, moist climates: a reduction of the pulse-rate, decrease in respiratory action, diminution in the number of red blood-corpuscles, increase in perspiration, reduction in saliva, gastric and pancreatic juices and bile.

Health Conditions Along the Panama Route.—At Panama the seasons are divided into two tol-

erably well defined periods: the dry, or winter, and the wet, or summer, seasons. By this accidental concurrence of the seasons of maximum moisture and maximum heat, the humidity and effluvia from marshes and swamps reaches its greatest possible amount.

For 55 per cent. of the time the winds blow from the northeast and northwest, and 35 per cent. of the time from the southeast and southwest.

The dry season includes the months of January, February, March and April, the rainy season occupying the remaining eight months of the year. During the dry season the average temperature at Colon for six years, 1882-7, was 79.5° F., with a monthly maximum of 90.9°, which occurred in January, and a monthly minimum of 68.4°, which was recorded for the same month. During the rainy season the maximum average temperature for any month occurred in October with a record of 91.9° F. The minimum of temperature for any month of the year was 66.9° F. for August.

The hourly variation in temperature is greatest during the dry season, when the change is, on an average, 7° F. between 4 P. M. and 7 A. M. each day. In the rainy season this difference is 5° F.

The humidity at Colon in 1881 was, on an average, 86 per cent. during the rainy season and 77 per cent. during the rest of the year. Only limited data are available concerning humidity, but the probability is that it is very high at most points on the Isthmus. As the climate of this insular country depends partly upon the influence of the sea, the temperature of the water of the Atlantic Ocean and that of the Pacific is interesting. On the line of the Panama Canal the temperature of the Atlantic is generally 9° F. higher than the Pacific in February with a difference of 1° F. in September. At Colon the mean temperature of the ocean is nearly that of the air, 79.90° F.

The barometric pressure is very uniform, especially in the dry season, from which it appears that severe storms are uncommon; yet northers occur occasionally and severe hurricanes have been known on the Atlantic coast.

As a result of fifteen years' records at Colon the annual precipitation in inches which was measured reached a maximum of 154.89 with a minimum of 116.36 and a mean of 130.20. Rainfall records for four years at Panama show a maximum of 84.73 inches, a minimum of 45.59 inches, and an average of 66.77 inches per year. At Culebra the records for three years showed the rainfall per year varied from 64.25 inches to 98.97 inches.

As to the forms of disease most commonly met with, Griswold says that four-fifths of all sickness at Panama are due to fevers. Severe bilious fevers, congestive fevers and Chagres fever are not uncommon. According to Buel, the most sickly period is September, October and November, during which time dysentery is very common, as is also a high degree of bilious fever which, in malignity and fatality, falls little short of yellow fever. Foreigners seldom, if ever, acquire the same immunity from local diseases as that enjoyed by the natives; they are frequently attacked by febrile disorders and in the interim suffer from the depressing and debilitating effects of the climate. In March, April and May fevers are at their minimum. Dysentery is common at the end of the rainy season and at the beginning of the dry season. Phthisis is prevalent among the natives, especially along the coasts. According to Wallis, "smallpox, yellow fever and paludal fevers in their infinite varieties and forms are never absent in these inter-tropical regions where they are truly endemic." Nelson, after an experience of five years at Panama, gives his approval of the statement long made with reference to the Isthmus, that it is the "Grave of the European." It has also been called the "Pest House of the Tropics," and Bigelow says that here truly "Life dies and death lives."

In the contracts let by the old Panama Canal Company, the latter was compelled to supply the labor. The total population of Panama was estimated at not above 150,000, and, as many thousand workmen were required for the work upon the canal, it was necessary to import labor from abroad. In the effort to supply the demand, many laborers were brought from the Island of Jamaica, but of these many soon fell sick and died, and a large number of the remainder left the work to escape a similar fate. Other workmen came from Carthagena, the British Antilles and the lower Mississippi Valley. Of all the labor employed, the most hardy workers, as regards ability to endure hardship and resist disease, were a tribe of Indians from the Magdalena River.

The sickness and loss of life among the men engaged at work upon the canal has been variously stated. Davidson declares that of a force of 7,000 men, the company reckoned that about 1,000 men were always in hospital. From other sources we learn that the sickness and death-rate among the laborers were very high. In Panama and its vicinity 37 engineers out of less than 100 are said to have died during the months of March and April, 1882. An observer declares "there was not a single French engineer who had been able to attend to the work beyond one year and a half, although the contract called for two." In September, 1884, it is said the Canal Company buried 654 officers and men. There were many sanitary abuses when the canal work was first begun, and the method of charging the contractors for the care of the men in hospital no doubt caused the laborers to be kept at work when they should have been under medical care.

The health conditions as officially reported by French authorities, do not show the high mortalities from diseases incident to the climate which have been indicated by travelers and other independent observers. But Heffenger declares that it was impossible for him to gain access to the health records of the Panama Canal Company

and that the impression gained by him after investigating the matter privately was, that the public reports were garbled and incorrect. Dr. Heffenger states that he was informed by a leading physician of Panama that in the first eleven months, during which preliminary work on the canal was under way, 65 officers and 800 men died of disease.

It is recorded by Liddell that of 382 patients treated by him between the middle of June and the succeeding May, 250, or more than two-thirds, were suffering from remittent fever with bilious, gastric or enteric complications. Referring to the importation of labor for the Panama Railroad, Liddell says that the services of laboring men from the United States could not be counted on for three successive months. Before the end of the second month one-half the force was on the sick list or enfeebled by sickness already sustained.

In this connection it is interesting to note that the Panama Railroad Company, which has had fifty years experience, along the line of the Panama Canal grants to its white employees from the United States two months vacation every year.

The route of the Panama Canal follows low-lying valleys from the Atlantic terminus to a point within a few miles of the Pacific. Here, at what is known as the Culebra ridge, there is a section of several miles of mountain through which a deep excavation must be cut. It is probable that a large number of laborers would have to occupy the position for eight years. Next in importance are excavations and other work between Culebra and the Pacific. There is a considerable diversity in the engineering problems connected with the Panama route, but the labor would be comparatively concentrated. Swamps, with the rank vegetation peculiar to the tropics, abound along most of the line. To the cost of construction the Isthmian Canal Commission has added 20 per cent. to cover engineering, police, sanitation and general contingencies. The same percentage has been allowed for the Nicaragua route. How much would be devoted to sanitation is not stated.

Health Conditions Along the Nicaragua Route.—Some 280 miles north of the Atlantic entrance to the proposed Panama Canal is the city of Grey Town, the eastern terminus of the projected route of the Nicaragua canal. Topographically the country traversed by the line of the Nicaragua Canal consists of a great, central, basin-like depression, enclosed by coastal mountain ranges, whose peaks occasionally attain a height of from 5,000 to 7,000 feet. The Central Basin is occupied by two great lakes, the waters of which flow eastward through valleys which open diagonally to the Atlantic Ocean. The central depression descends to the Pacific through a short and narrow valley in the western coast range. The route is marked by swamps, lagoons and river bottoms heavily overgrown with rank tropical vegetation. By far the largest share of the estimated cost of constructing the Nicaragua Canal is allotted to that part of the line which lies east of the lakes. Here are located extensive river and harbor improvements, several locks and the Conchuda Dam, whose site is between Ochoa and Lake Nicaragua. It is thought that the canal would be eight years in building.

Much less is known about the climate and health conditions of Nicaragua than Panama. According to all sources of information, the temperature is fairly uniform throughout the year. The report of the Isthmian Canal Commission just published states that the thermometer seldom reaches 95° F. nor falls below 70° F. The humidity is usually high, particularly on the eastern slope. As recorded for several stations in 1898 the humidity was never below 58 per cent. and generally above 80 per cent. It has been declared that the locality is beyond the cyclonic disturbances of the West Indies and that heavy storms are rare, yet authentic accounts exist which show that northers and other similar atmospheric disturbances have occurred at infrequent intervals along the Atlantic coast. The northeast trade winds predominate.

Rainfall records show that there is no definitely wet nor dry season on the eastern slope, but in the region of Lake Nicaragua and on the west coast there is a distinct dry season from about the 1st of December to the middle of May, during which rain seldom falls. During the dry season the prevailing winds blow from the Atlantic coast and the moisture contained in the atmosphere is precipitated before it reaches the central and western watersheds.

The rainfall at the Atlantic end of the Nicaragua Canal route is the heaviest yet recorded for the American continent. The annual rainfall at Grey Town averages 260-270 inches and has twice reached nearly 300 inches. Points at which rainfall was noted in 1900 were: Grey Town, 266.10 inches; Ochoa, 158.83 inches, and Fort San Carlos, 89.34 inches. In 1898 the rainfall at San Juan (Grey Town) was 201.64 inches; Ochoa, 170.84 inches, and Brito, the Pacific terminal, 94.88 inches. The heaviest recorded fall of rain in a short period occurred at Lake Silico, November 4, 1899, when 10.5 inches fell in six hours, an average of 1¾ inches per hour. On the same date 12.48 inches of rain fell in 24 hours at Grey Town. A fall of four or more inches per day is not uncommon.

It is the testimony of disinterested observers that both coasts of Nicaragua are malarious with a considerable amount of suffering from malarial cachexia and enlargement of the spleen. Dysentery is one of the severe diseases of the country. A prevalence of fever of the pernicious type has been noted particularly in the western portion of the country. The fever is generally hepatic and jaundice and hematemesis are usually present. The mortality from pernicious fever is very high. As this disease carries so many of the characteristic symptoms of yellow fever, Stitt declares that able physicians frequently pronounce the two diseases to be identical.

Among the diseases not epidemic but prevalent, may be mentioned those of an enteric nature, affections of the liver such as hyperemia and tropical abscess, intermittent and remittent fevers and pulmonary tuberculosis. The climate of the lake region is said to be particularly unfavorable to persons suffering from phthisis. The yearly reports made by the Maritime Canal Company of Nicaragua to the Secretary of the Interior of the United States, convey the impression that the health of the employees engaged upon the canal construction was satisfactory. About 1⅓ per cent. of those actually in hospital died, including the patients who were admitted for the treatment of accidental injuries. About 51 per cent. of all cases of sickness were fevers; there were no deaths from enteric diseases, and only two-thirds of 1 per cent. of the cases in hospital died of diseases contracted in the country.

Commenting upon the records of the Maritime Canal Company the Isthmian Canal Commission of 1899-1901 observes that "These operations, however, were of a preliminary character, employing but a limited number of men. It is probable that when 10,000 or 20,000 men are assembled, and the rank soil is being turned up over a widely-developed line of works, the experience will be different." There is very little impartial or antagonistic criticism available concerning the health conditions which obtained at the works of the Maritime Canal Company, for very little attention has been given to this project except by Americans who have long been prejudiced in its favor.

Comparison Between the Panama and Nicaragua Routes.—A comparison of the conditions which make for and against health, along the proposed lines of the Panama and Nicaragua Canals may be summed up conveniently under the two following heads:

I. Which route would probably be freer from disease during the work of construction?

II. Which canal would be more favorable to health after it was built?

In discussing these topics it will be convenient to note some of the most unfavorable conditions common to both routes and suggest very briefly means by which the rates of sickness and death may be kept as low as practicable.

I. *Health Conditions During Construction.*—The greatest difference in climate between the lines of the Panama and Nicaragua Canals is in rainfall. Panama has a dry season of four months with a rainy season of eight. No rain at all falls during the winter months and in the rainy season the precipitation occurs mostly as heavy showers which come on in the afternoon. On most of the Nicaragua line, particularly at the site of the great dam and about Grey Town, rain falls throughout the year. The immediate effect of the constant rain in Nicaragua is to keep laborers and others exposed to the elements in a drenched condition. Wet clothes taken off at night are put on damp the next morning and worn so through the day. Sleeping garments removed after a night's rest are placed in rubber receptacles so they may be dry at night. The effect upon health of this constant wetting may be imagined. It is not reasonable that the human system should be able to long stand the debilitating effects which the wet apparel produces. Diseases of the respiratory organs, rheumatism and fevers are consequently invited by the climatic conditions which occur between the lakes and the Atlantic terminus of the Nicaragua Canal. The western part of the route appears to be very similar to the Panama country so far as climate is concerned.

The range of temperature, so far as the records at hand indicate, is somewhat greater at Nicaragua than at Panama. Daily changes of temperature, however, do not seem to be quite so marked. The humidity is higher, and the soil, by reason of a greater length of low swampy territory along the Nicaragua line, makes the northern route less acceptable than the Panama Canal would be from this standpoint of health.

There is little difference in the nature of the diseases which are indigenous to the countries along the two routes. The history of the Panama Canal country is a black one, but in considering the records of sickness along this route, it must be remembered that grave sanitary errors were committed from the beginning, and that unfavorable accounts arising probably in some cases from commercial and national prejudices have been collecting for a long time. The situation is very different with respect to Nicaragua. The country is comparatively new and no such damage to its reputation has occurred. If it is said that but little disease can be charged against Nicaragua the reason is probably because little experience of any kind has been had there.

From the evidence at hand it is inferred that dysentery, malarial and other fevers are as much at home under the conditions of climate and soil which exist in Nicaragua as they are at Panama and that smallpox and many minor tropical diseases are probably endemic in both countries. The climate in each case predisposes the native and foreigner to sickness and favors the progress of the worst diseases which may be brought into the country.

The ordinary habits of the natives and visitors who stay any length of time on the Isthmus are not calculated to increase bodily vigor and natural resistance to disease. Carelessness to exposure, indifference to obvious dangers of diet, lack of proper attention to bodily irregularities and a strong appetite for spirituous liquors are conditions which render the people of the Isthmus especially liable to disease.

Following the precedent established by the Suez Canal enterprise and adopted by the promoters of the Panama and Nicaragua Canals, a department of health will in all likelihood be organized. The work which will naturally come before this sanitary organization will include the procuring and protection of pure water supplies, and the prompt and permanent disposition of the daily wastes

which will occur among the thousands of laborers who will be gathered together in camps and settlements. The housing and provisioning of the men will no doubt form a division of the work, as will the regulation of their hours and habits of toil and recreation. Medical inspections will be required in order to detect the presence of diseases and insanitary conditions, and hospitals with branches along the line will be necessary to care for those who will inevitably suffer from accident and sickness. If an arrangement can be made by which the physical condition of the laborers is examined, and perhaps vaccination practised, before they are allowed to embark from their home ports for the works, the subsequent labor of the sanitary organization will be greatly lightened.

The type of physique which has been found most able to resist the unhealthful conditions of the climate of the Isthmus closely approaches the best types already found there and in the neighboring islands and on the Gulf coast of the United States. The foreigner least susceptible to disease in these tropical countries is a man of medium stature, square frame, dark complexion, thick skin, and mature age.

II. *Health Conditions After Completion of the Canal.*—The health conditions which are likely to obtain at the canal after its completion are worthy of consideration since a large population will probably gather along the route and an immense amount of traffic will pass through the great waterway. Tributary to the Nicaragua route there is a naturally rich and extensive country which would be opened up to traffic. On the line of the Panama waterway the country is rugged, sparsely settled and much less productive. At the present time the population along the Nicaragua route is slight and cities near its terminals are not yet built. At Panama a railroad which has been established for fifty years nearly parallels the line of the canal. Two well-established cities are situated at the ends of this route.

After the canal is built, infectious diseases will almost inevitably be brought to the people of the Isthmus by the large amount of traffic which will result. Vessels will come from the cholera centers of Hong Kong, Calcutta, Bombay, Madras, Singapore and the Straits settlements; from the plague foci of China, India and Japan and from the yellow-fever ports of Brazil, Mexico and those islands of the West Indies which lie between 61° and 85° west longitude.

Comparing the two routes across the Isthmus from this standpoint, it is plain that the Panama Canal has a very marked advantage over the line which would pass through Nicaragua. It is much shorter. Ships in transit would be able to pass from ocean to ocean by the Panama Canal in twelve hours, while by the Nicaragua Canal thirty-three hours would be consumed. It may be urged that communication with the land in either case could be avoided, and that an efficient sanitary police could effectually protect the people and shipping against mutually communicating disease. Unfortunately, further thought shows that this would be a difficult matter. The temptation for sailors and others to seek the relaxation of a few hours on shore in the middle of a long voyage and under conditions of a peculiarly alluring nature while the ships are slowly passing through the locks and narrow reaches of the canal is not to be denied. If to this temptation is added the certainty of being able to overtake vessels by railway after a night's debauch it is not clear how the Isthmus can certainly be prevented from becoming a focus of disease as well as a focus of trade.

It is extremely important that this great highway of commerce should be kept entirely free of epidemics of infectious diseases for the burdens which would be put upon shipping in the event, for example, of cholera becoming prevalent along the canal would go far to offset the advantages to be gained by making the short cut from ocean to ocean. Nor would the fact that a vessel had loaded her cargo at a healthy port relieve her from suspicion of carrying disease. It is doubtful if the quarantine officers of any healthy city would admit to *pratique* a vessel which had passed a day and a half in an infected country, whether the original ports of departure of that ship had been in a healthy condition or not.

Another effect which the opening of the canal is liable to have upon public health will be that due to the improved chances of carrying disease between ports which will be brought nearer together by the canal. The southern ports of the United States and the Pacific coast will be brought in much closer contact with the unhealthy cities of South America and the East by the opening of a trans-Isthmian canal. The obvious remedy here is the cleaning up of these unhealthy centers; but meanwhile the insanitary condition of many of the ports of trade, both in the United States and South America, makes the danger dependent upon a closer and more extensive traffic among them.

Summary of Conclusions.

The principal conclusions reached in the foregoing inquiry may be conveniently brought together in the following catagorical order:

1. Both the Panama and Nicaragua routes pass through a country which is extremely unfavorable to health.

2. The climate of Nicaragua and Panama differ chiefly with respect to rainfall, the precipitation on the Panama route being distinctly the less unfavorable to health.

3. Considerations of soil, topography and the nature of the engineering work to be done are in favor of Panama. Fewer men would be required; they would be concentrated and, hence, their health could be more easily protected.

4. There is practically no difference in the nature of the diseases to be anticipated, nor in the precautions to be taken to protect health in either case.

5. After construction, the difficulty of control-

ling health conditions along the line would be greater on the Nicaragua route.

6. The shorter Panama route would cause passing vessels to be exposed to the possibilities of infection for a much briefer interval. The danger of communicating diseases to and from the Isthmus is fairly represented by the difference in time which it would take ships to pass from ocean to ocean by the two routes.

7. The likelihood of the canal becoming a disease focus, thus interfering with commerce, by requiring all healthy ports to quarantine against ships passing the Isthmus, is much greater in the case of Nicaragua than Panama.

8. Although the Panama health records are much darkened by heavy losses of life by disease, this is not to be construed as evidence of the existence of conditions favoring a greater immunity from sickness along the Nicaragua line. More lives have been lost at Panama because more lives have been unnecessarily exposed. The experience of Panama is to be taken as a warning of conditions which are liable to be repeated on either route.

9. Whichever canal is selected, extraordinary care will be required to maintain satisfactory health conditions during construction and after completion of the work.

10. Plans and preparations in detail for the organization of an efficient sanitary and medical department should be made as early as possible so that the measures necessary for the prevention of disease may be carried on in harmony with the engineering projects.

Indications for Amputation.—In cases of severe phlegmon, gangrene or sepsis, the question of amputation is often difficult to decide. H. Wolff (Münch. med. Woch., Nov. 26, 1901) lays down the indication as follows: (1) When, despite free incision, the acute progressive character of the infection and the general symptoms persist; (2) when the local symptoms have come to a standstill and life is still endangered through the absorption of bacteria or their toxins; (3) when the local and general process shows signs of abating, but the limb is useless to the owner in the end.

THE TRIAL, EXECUTION, AUTOPSY AND MENTAL STATUS OF LEON F. CZOLGOSZ, ALIAS FRED NIEMAN, THE ASSASSIN OF PRESIDENT M'KINLEY.

BY CARLOS F. MACDONALD, A.M., M.D.,

OF NEW YORK;

PROFESSOR OF MENTAL DISEASES AND MEDICAL JURISPRUDENCE IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; EX-PRESIDENT OF THE NEW YORK STATE COMMISSION IN LUNACY.

The terrible shock which the assassination of President McKinley by Leon F. Czolgosz at Buffalo, New York, on September 6, 1901, imparted to the entire civilized world, and which naturally engendered in the public mind a mingled feeling of horror, vindictiveness and revenge—a feeling which was exceeded only by the profound sense of sorrow and depression which took possession of the people when a few days later it was realized that despite the highest efforts of surgical and medical skill a fatal result to the distinguished victim was inevitable—naturally suggested, both to the lay and medico-legal mind, the need of inquiry as to the mental status and responsibility of the perpetrator of so repulsive and atrocious an act. Moreover, there are many persons who are disposed to hold that the enormity of such a crime is in itself sufficient evidence to warrant the opinion of the existence of insanity, merely because it seems to them inconsistent with the principles of ordinary rational conduct, even though aside from the act itself there be nothing in the entire life and conduct of the individual that is suggestive of mental disease. On the other hand, there are many who, in view of the magnitude of the crime, would oppose the granting of exemption from the ordinary consequences of capital offences even though the offender were a raving maniac. Suffice it to say that the position taken by such persons, in either case, is untenable and would be an untrustworthy test of responsibility as regards the ends of justice, whether viewed from a legal or a medical standpoint.

It need scarcely be said that the question as to whether or not a certain act is the offspring of mental disease, cannot always with safety be determined by the act itself, but must be determined by all the attendant circumstances leading up to and surrounding the act.

"An act of violence," says Ray, "must not be attributed to insanity merely because to a person of high culture and correct morals, it seems inexplicable on the ordinary principles of human conduct."

According to the Code of Criminal Procedure of the State of New York, Section 21, the legal test of mental unsoundness, as applied to criminal cases, is based on the assumption that insanity is a question of law to be determined by the Court, and that the question of responsibility in mental disease hinges upon a knowledge of right and wrong as to the particular act at the time it was committed; whereas medical science holds that insanity, in its relation to crime, is always a question of fact to be determined like any other fact in evidence, aided, of course, in such case, by the interpretation of expert opinion evidence, and that whenever its presence can be so determined, the accused should be absolved from responsibility, irrespective of the form or degree of his mental disease or the nature of the act committed. "All that medical science has to do in any such case," says Dr. John P. Gray, "is to say whether the deed springs from disease or not. If it does not, the man is responsible, however, ghastly, seemingly purposeless or vindictive the act may be." In other words, medical science holds that the whole question of responsibility should rest upon the pres-

ence or absence of mental disease, and not upon a knowledge of right and wrong as regards the nature and consequences of the act in question, and that that which in fact is a condition of mental disease cannot in law be a condition of mental health.

The question to be determined, then, in the case of Czolgosz, from the legal standpoint, as embodied in the Code of Criminal Procedure of the State of New York, was: When Czolgosz shot the President did he know the nature and quality of the act he was doing, and that the act was wrong? If this question could be determined in the affirmative, then he was responsible under the law and punishable for the offense which he committed, even though he was medically insane, so to speak.

On the other hand, the question to be determined from the standpoint of medical science was: Was Czolgosz at the time he committed the act a victim of mental disease or mental unsoundness? If so, according to the dictum of medical science, he was not responsible and hence not punishable for the act he committed. These are the sole questions upon which the guilt or innocence of the accused must rest, whether in the eyes of the law or in the judgment of medical science, and it follows logically that if he were guilty of crime owing to the absence of mental disease, he was equally guilty within the intent and meaning of the statute. Such being the case the subject of the responsibility of the accused resolves itself into a question of health or disease—sanity or insanity. Hence the application of the legal test may be dismissed from further consideration here and we may proceed to consider the question of his responsibility from a medical point of view.

The Trial.

The trial of Czolgosz which took place in the city of Buffalo, N. Y., on September 23-4, 1901, Hon. Truman C. White, Presiding Justice, was neither attended by delay "nor harassed by the trivial technicalities of the law." The "machinery of justice" moved so smoothly and so rapidly that the jury was procured, the case tried and a verdict of guilty rendered within a period of two court days with sessions from 10 to 12 o'clock in the forenoons and 2 to 4 o'clock in the afternoons, the time actually occupied being about eight and a half hours in all. The proceedings were marked by no melodramatic or sensational episodes or unseemly wrangle among counsel; while the fact that, under the extraordinary circumstances, the trial was not anticipated or interrupted by any riotous demonstration against the prisoner—any attempt at mob or lynch law—when he appeared in public, affords striking proof of the respect for law and order which prevails in the community where the trial was held. Czolgosz was brought into court closely guarded by a double cordon of police and handcuffed to an officer on either side. He was neatly dressed and cleanly in appearance, his face clean-shaven and hair neatly combed.

The preparation and trial of the case on the part of the people by the Hon. Thomas Penny, District Attorney, and his assistant, Mr. Haller, was well nigh faultless. Shortly after his arrest the District Attorney procured from Czolgosz a statement several pages in length which was taken down in longhand, in narrative form, each page of which he signed after himself making corrections and revisions as to matters which he claimed the reporter had misapprehended. This statement gave in detail facts concerning his premeditations and preparations for the crime, also his movements for some time prior, and up to the time of the shooting. The District Attorney also within a few hours after the crime was committed, proceeded to put the prisoner under the observation of local experts in mental disease, namely, Drs. Joseph Fowler, Police Surgeon, Floyd S. Crego and James W. Putnam. These physicians had free access to him, down to and during the trial—covering a period of nearly three weeks during which they examined him repeatedly and made a careful study of his case with reference to his mental condition. The District Attorney also permitted the experts on either side to confer together freely, and allowed those for the defense to have free access to all facts and information relative to the case in his possession—a proceeding which in effect was equivalent to the appointment of a commission of five experts—three for the prosecution, and two for the defense—to determine the prisoner's mental condition. This course on the part of the District Attorney, marks a new departure in the methods of getting expert evidence in criminal trials where the question of mental responsibility is involved, which is to be highly commended as a practical measure tending to eliminate much superfluous testimony and at the same time to minimize the danger of contradictory expert opinions.

In view of the great importance of the case, it is regrettable that no experts were called to testify at the trial as to the prisoner's mental condition in order that it might appear on the record of the trial that his mental state was inquired into and determined by competent authority. Had the experts on either side been given the opportunity of thus stating officially their unanimous conclusion, together with the grounds on which it was based and the methods by which it was reached, it would have left in the public mind no room for reasonable doubt as to its absolute correctness and that it had been arrived at only by the rules of professional conduct governing the examination of such cases.

The attorneys assigned by the court to the defendant, at the request of the Bar Association of Erie County, were ex-Judge Loran L. Lewis and Robert C. Titus, both prominent lawyers and highly-respected citizens of Buffalo. For obvious reasons these gentlemen were reluctant to undertake what they regarded as a most distasteful task, and consented to do so only from a high sense of duty to the public, at the urgent solicitation of the President, Hon. Adelbert Moot, and other prominent members of the Bar Association, on Saturday, September 21st, preceding the trial, which began on Monday, the 23d.

Respecting the defense, it appears that substantially no preparation was made beyond a fruitless effort of counsel to confer with the prisoner and the examinations made of him at their request by Dr. Hurd and the writer with reference to his mental condition, and a verbal statement by them to counsel of their conclusion that he was not insane. It also appears that no plea was entered by the attorneys for the defense, but Czolgosz, speaking for the first time in court, entered a plea of guilty to the indictment, which plea the court promptly rejected and directed that one of not guilty be entered on the record for the defendant.

Each juror on qualifying said, in answer to the usual question, that he had formed an opinion as to the guilt of the prisoner, but that his opinion could be removed by reasonable evidence tending to show that the defendant was innocent. And yet, to one accustomed to being in court and observing jurors when qualifying, it was difficult to avoid the impression that each of the jurors in this case held a mental reservation to convict the prisoner. Had Czolgosz been on trial for the murder of a common citizen, instead of the President, it is safe to say that not one of the jury as completed would have been accepted by the defence; and instead

of getting a jury in approximately one hour and a half, that feature of the trial alone would probably have occupied several days.

Having in view the nature and importance of the case, the fact that no testimony was offered on the defendant's behalf and that practically no defence was made, beyond a perfunctory examination of jurors and a mild cross-examination of some of the people's witnesses, which was limited to efforts to elicit information respecting the President's condition during his illness and of his body after death, and a summing up by one of the counsel—Judge Lewis—which consisted mainly of an apology for appearing as counsel for the defendant and a touching eulogy of his distinguished victim, renders the case in this respect, a unique one in the annals of criminal jurisprudence.

The jury retired for deliberation about 4 p. m. and returned in less than half an hour with a verdict of guilty of murder in the first degree. Czolgosz heard the verdict of the jury standing and without appreciable display of emotion. Several of the jurors were interviewed after the trial and were reported to have said that the jury was in favor of conviction unanimously from the first and could have rendered a verdict without leaving their seats, but deemed it best to make a pretense of deliberation "for appearance sake." Czolgosz was remanded to jail for two days and on Thursday, September 26th, was sentenced to be executed by electricity at Auburn Prison in the week beginning October 28, 1901.

When Czolgosz returned to his cell after his conviction he ate a hearty supper and soon thereafter went to bed and slept continuously until midnight, when the guard was changed, when he awoke for a few minutes, and then slept again until 6 a. m., when he arose and took a short walk in the cell corridor, after which he made a careful toilet, and at 7:30 partook of a hearty breakfast. He talked freely, as usual, on ordinary topics, but maintained his usual silence respecting his crime and would not talk of the trial or the verdict. On Thursday, September 26th, he was removed from the Buffalo jail to the State Prison at Auburn, N. Y., where he was confined in a "death cell" until his execution took place.

The Execution.

Czolgosz was executed by electricity on the morning of October 29, 1901. The official witnesses, consisting of the Superintendent of State Prisons and other prominent New York State officials, several physicians, three representatives of the respective press associations, Mr. Spitzka and others, and the official physicians—Dr. John Gerin, Prison Physician, and myself—having been assembled in the execution room and having received the usual admonition from the Warden as to maintenance of order during the execution, the prisoner was conducted to the room a few minutes after 7 a. m. Every precaution was taken by the Warden, who had immediate charge of the execution, to minimize the opportunity for notoriety or sensationalism on the part of the prisoner as well as to insure that his taking off should be effected in an orderly and dignified manner.

As Czolgosz entered the room he appeared calm and self-possessed, his head was erect and his face bore an expression of defiant determination. The guards, one on either side, quietly and quickly guided him to the fatal chair, the binding straps were rapidly adjusted to his arms, legs and body, and the head and leg electrodes were quickly placed *in situ* and connected with the wire which was to transmit the lethal current through his body. These preliminaries occupied about one minute. Czolgosz offered no resistance whatever, but during the preparations addressed himself to the witnesses in a clear distinct voice in the following significant language: "I killed the President because he was the enemy of the good people—the good working people. I am not sorry for my crime. I am sorry I could not see my father." At this moment, everything being in readiness, the Warden signaled the official electrician in charge of the switch, who immediately turned the lever which closed the circuit and shot the deadly current through the criminal's body, which was instantly thrown into a state of tonic spasm involving apparently every fiber of the entire muscular system. At the same time, consciousness, sensation and motion were apparently absolutely abolished.

Two electrical contacts were made, occupying in all one minute and five seconds. In the first contact the electro-motive pressure was maintained at 1,800 volts for seven seconds, then reduced to 300 volts for twenty-three seconds, increased to 1,800 volts for four seconds and again reduced to 300 volts for twenty-six seconds—one minute in all—when the contact was broken. The second contact, which was made at the instance of the writer as a precautionary measure, but which was probably unnecessary, was maintained at 1,800 volts for five seconds. That conscious life was absolutely destroyed the instant the first contact was made was conceded by all of the medical witnesses present; also that organic life was abolished within a few seconds thereafter.

Czolgosz was pronounced dead by the attending physician and several of the other physicians present, after personal examination, in four minutes from the time he entered the room; one minute of this period, as already stated, was occupied in the preliminary preparations, one minute and five seconds in the electrical contacts, and the remainder of the time in examinations by the physicians to determine the fact of death.

The physicians present at the execution and at the autopsy were Drs. H. O. Ely of Binghamton, N. Y., W. A. Howe of Phelps, N. Y., G. R. Trowbridge of Buffalo, N. Y., W. D. Wolff of Rochester, N. Y., and C. R. Huntley of Buffalo.

The Autopsy.

The autopsy was made by Mr. Edward A. Spitka under the direction of the official physician, Dr. Gerin and myself. The examination occupied about four and a half hours and embraced a most careful gross examination of all the viscera, attention being especially directed to the brain and its meninges. The accompanying masterly description of the postmortem findings, and especially of the condition and anatomical structure of the brain by Mr. Spitzka, leaves nothing to be said here upon this point beyond the fact that the autopsy revealed no evidence whatever of disease or deformity of any of the bodily organs including the brain, which was normal in size, shape, weight and appearance and was well developed in all respects, a conclusion which was concurred in by all of the physicians present, several of whom had witnessed the execution.

In deference to the expressed wish of the relatives of Czolgosz, and for reasons of a sentimental nature on the part of the State authorities, the Prison Warden declined positively to allow any portion of the body to be removed from the Prison. Consequently, and regrettably, it was impossible for the examiners to retain honorable possession of any portion of the brain for microscopic examination and study. Accurate measurements, however, of the head and its appendages, of the face and of the exterior and interior of the skull, together with detail anatomical drawings and descriptions of the brain were made; also plaster moulds of

the head from which a cast was subsequently made and photographs of the same—full face and profile—taken. These measurements, together with plates of the drawings and photographs are presented in Mr. Spitzka's report of the autopsy.

In view of its great importance both to medical science and to medical jurisprudence, the writer regards it as fortunate that the State was able to secure the services of so able a brain anatomist and skilled operator and draughtsman as Mr. Spitzka to make the post-mortem examination.

The Mental Status.

On Thursday, September 19, 1901, I received a telegram requesting me to meet Mr. Adelbert Moot, President of the Erie County Bar Association, in Buffalo, New York, on the following morning. On my arrival in Buffalo the next day Mr. Moot informed me that he had sent for me for the purpose of requesting me to inquire into the mental condition of Leon F. Czolgosz, confined in the Buffalo jail under indictment for the murder of President McKinley, and whose trial was to begin on the following Monday. Mr. Moot further stated in substance that three local experts had already examined the prisoner for the District Attorney, but in view of the enormity of the offence and the fact that there obviously could be no legitimate defense other than insanity, it was deemed important, in the interests of justice, that his mental condition should be investigated by other experts acting in behalf of the defence, or at least independently of the prosecution, to the end that the prisoner should be accorded every legal right, there being no desire to convict him if he were not mentally responsible, and that I had been selected for this responsible duty. With a deep sense of the responsibility involved, I consented to act, provided it should be distinctly understood that I was not there as a partisan expert in behalf of either side, but simply in a professional capacity to aid in determining the real mental state of the prisoner, and providing further that my selection would be acceptable to the eminent counsel whom the Bar Association had selected for the defence, should they decide to accept that duty, a matter which was then undecided. On the following morning—Saturday—Mr. Moot informed me that the gentlemen referred to had consented to act and invited me to meet them in conference, which I did, and which resulted in their requesting me to proceed at once to examine into the prisoner's mental condition and to report my conclusion to them as soon as I had reached one. They also assented readily to my proposal to invite Dr. Arthur W. Hurd to become associated with me professionally in the case, Dr. Hurd being the Superintendent of the Buffalo State Hospital for the Insane and a competent alienist of large experience in mental diseases. It was also agreed that we should be allowed to confer freely with the District Atorney and with the experts for the people, after completing our personal examination of the prisoner. Being unable to establish communication with Dr. Hurd before evening of that day and in view of the short time intervening before the trial, I decided to make a preliminary examination of Czolgosz alone, and did so that afternoon in the District Atorney's office, first disclosing to him my identity and the object of my interview and informing him of his legal right to decline to answer any question I might ask him.

I examined him again on the following day, Sunday, in the jail, jointly with Dr. Hurd and in the presence of one of his guards who was questioned at length, respecting his observations of him in the jail, as to his habits of eating, sleeping, talking, reading, etc. We subsequently interviewed the District Attorney and the Superintendent of Police, General Bull, who gave us all the facts and information in their possession respecting the case. The statement which Czolgosz made to the District Attorney shortly after his arrest throws much light on his mental condition on the day of the crime, but that official deemed it his duty to refuse to allow me to publish it. We also conferred at length with the people's experts, Drs. Fowler, Crego and Putnam, who stated to us separately and in detail their observations and examinations of him. We also observed him carefully in the court-room throughout the trial.

After our examination of Czolgosz on Sunday, we reached the conclusion, independently of each other, that he was sane and we so informed his counsel on Monday morning before the trial began.

It should be said that owing to the limited time—two days—at our disposal prior to the trial and the fact that his relatives resided in a distant State and were not accessible for interrogation, we were unable to obtain a history of his heredity, beyond what he himself gave us.

Czolgosz, as he appeared at the time of my examinations of him at Buffalo, may be described as a well nourished, rather good-looking, mild-mannered young man, with a pleasant facial expression; features, regular; face, smooth-shaven and symmetrical; mouth and ears well formed and symmetrical; teeth, none missing but in poor condition from neglect; tongue, clean; palate, fauces and uvula, normal in appearance; eyes, blue and normal in expression; pupils, equal in size and normally responsive to light and accommodation; hair, light brown and slightly curly; stature, medium—five feet seven and a half inches—and weight (estimated) about 140 pounds. The extremities were in all respects normal. The external genitals were normal, excepting two small, flat, unindurated cicatrices on the mucous surface of the prepuce, probably the result of previous chancroids, although he denied having had venereal disease other than gonorrhea. There were no signs of specific nodes or periosteal tenderness over the usual sites of these lesions, nor was there any evidence upon the head or body of traumatism, excepting a slight deviation of the nose due to a blow which he received at the time of the assassination, and a superficial, perpendicular cicatrix on the left face which he said was the result of a slight injury he received when working in a barbed-wire factory. There were no tremors or twitchings of the facial muscles, tongue or hands. The pulse and temperature and skin were normal, as also were the special senses, knee reflexes, coordinating power and the sensory and motor functions. Finally, a careful inspection of the entire visible body failed to reveal the presence of any of the so-called stigmata of degeneration. The almost perfect symmetrical development—especially of the head and face—is a noteworthy feature in Czolgosz's case, although had deviations been found the fact would have had little weight as tending to show mental disease or degeneracy, as marked asymmetries, both cranial and facial, are frequently observed in persons who are quite sane and above the average in mental capacity.

In answer to questions he stated, in substance, that he was born in Detroit, Michigan, of Polish parents; that he was twenty-eight years of age, unmarried and a laborer by occupation; that he was a Romanist, originally, but had abandoned that faith several years ago because he no longer believed in it; that he attended the common schools as a boy and had learned to read and write; that he had used beer and tobacco, but not to excess; that he had done various kinds of unskilled labor, such as farming, factorying, etc.; that

his mother was dead and his father, one brother and a married sister were living; that so far as he knew there was no insanity in his family, and that he had not suffered any serious illness or injury during his life-time; that he had never been subject to fits, spasms or vertigo; that he usually ate and slept well, and that his bowels were always regular. He admitted having had sexual intercourse with women, but denied masturbation or other unnatural practices.

Careful inquiry failed to elicit any evidence of delusion, hallucination or illusion. When questioned as to the existence of enemies, persecutions or conspiracies against him, he replied in the negative. He evinced no appearance of morbid mental depression, morbid mental exaltation, or of mental weakness or loss of mind; nor did he display any indication of morbid suspicion, vanity or conceit, or claim that he was "inspired" or had "a mission to perform," or that he was subject to any uncontrollable impulse. In fact, as regards the existence of evidences of mental disease or defect, the result of the examinations was entirely negative. On the contrary, everything in his history, as shown by his conduct and declaration, points to the existence in him of the social disease, Anarchy, of which he was a victim.

My last examination of Czolgosz was made jointly with Dr. Gerin, Physician of Auburn Prison, the evening before his execution. This examination revealed nothing either in his mental or physical condition which tended to alter the opinion I gave to his counsel at the time of his trial, namely, that he was sane—an opinion which was concurred in by all of the official experts on either side, namely, Drs. Fowler, Crego and Putnam, for the people, and Dr. Hurd and myself for the defence, also by Dr. Gerin, the only other physician who examined him. Furthermore, the prisoner's manner, appearance and declarations in the execution room, together with the postmortem findings, corroborated most conclusively the original opinion as to sanity, while his dying declarations that he killed the President because he regarded him as "an enemy of the good people—the good working people," and that he was not sorry for his crime, all tend to stamp him as an Anarchist. In fact, his bearing and conduct from the time of the commission of the crime to his execution were entirely consistent with the teachings and creed of Anarchy. Moreover, neither the three careful personal examinations which I made of him—one alone, one with Dr. Hurd and one with Dr. Gerin—the measurements of his body by the Bertillon system nor the postmortem findings, disclosed the slightest evidence of mental disease, defect or degeneracy. This opinion is confirmed by the people's experts who repeatedly examined him and observed him from time to time, from the day of the assassination to the close of the trial, and by Dr. Gerin the physician of Auburn Prison, who observed him carefully during the four weeks that he was in that institution awaiting execution. Dr. Gerin has had exceptional opportunity for the study of criminals, both sane and insane, in his capacity as prison physician and, previously, as assistant physician at the State Hospital for the Criminal Insane.

If Czolgosz was a victim of mental disease the question would naturally arise as to what form of that disorder he was suffering from. If, in answer to this question, we undertake to make a diagnosis by exclusion, we find the following results: There was absolutely no evidence of insane delusion, hallucination or illusion. There was none of the morbid mental exaltation or expansiveness of ideas that would suggest mania in any form, none of the morbid mental gloom and despondency of melancholia, none of the mental weakness of dementia, none of the conjoined mental or motor symptoms that are characteristic of paresis, nor was there anything in his manner, conduct or declarations that would suggest the morbid vanity and egotism, the persecutory ideas or the transformation of personality which usually characterize paranoia or systematized delusional insanity. In fact, at no time during the period from his arrest to the time of his execution did he exhibit any of the mannerisms, boastful display, etc., or claim to have a "divine inspiration" or "a mission," or make any complaint or suggestion of personal wrongs and persecutions which are so characteristic of paranoiacs; nor did he, during his trial, or subsequently, evince any indication of satisfaction or delight at being the central figure of the occasion and the observed of all the observers which he was; nor was there any attempt on Czolgosz' part to simulate mental disease. The refusal to talk with his counsel was perfectly consistent with the views which he expressed to the District Attorney soon after his arrest, namely, that he did not believe in law and that he wanted no counsel. He did, however, converse with others, namely, the District Attorney from time to time before his trial, also with his guards at the Buffalo jail, with whom he frequently walked in the corridor fronting his cell for an hour or two at a time, conversing with them intelligently the while and making his wants as to bathing, toilet, tobacco, etc., known in a natural manner. He also conversed freely with the people's experts in their earlier examinations of him, and talked, though not so freely, with Dr. Hurd and myself, and when on arraignment for trial and formally asked to plead he promptly arose from his chair and answered in a clear voice, "Guilty." He also responded promptly when directed by the clerk of the court to "stand up and look upon the juror" as each of the jurors were sworn, and resumed his seat in each instance at the proper time. Beyond this he remained mute while in the court-room, and yet to anyone who observed him closely it was apparent that he was fully aware of and attentive to the proceedings.

A recent writer—an eminent alienist—discussing the mental state of Czolgosz says:*

"We can perceive no indications of mental disease in Czolgosz, and were the absurdity of his statements and acts to be a criterion of mental unsoundness we should have to establish a new category of insanity for the reception of the various groups of Anarchists—not to mention other terrorists. * * *

"We deem it an error to regard Czolgosz's mutism in court when called on to plead and before his counsel as an attempt to simulate insanity. This conduct is in line with his rôle expressed in the theatrical declaration, 'I am an Anarchist and have done my duty.' As it was his 'duty' to slay the President it is his duty to go to his death with his lips sealed, and with this intent, first the plea of guilty and his conduct are perfectly consistent. He shows no reluctance to converse on matters disconnected from the crime, nor even of matters connected therewith provided they do not touch its preparations and thus betray his associates.

Aside from his reticence to his counsel there was nothing in Czolgosz's manner, appearance or declarations that was indicative of insanity or of simulating. His reticence toward his counsel, as already intimated, was entirely consistent with his expressed disbelief in government and in law and his declaration that he shot the President with a clear knowledge of the nature and consequence of the act; and, while he pleaded guilty in court and also proclaimed when he went to his death his reason for committing the crime, and declared that he was not sorry therefor, in a manner which clearly

*"The Mental Status of Czolgosz and Assassins Generally," by E. C. Spitzka, M.D. The Medical Critic, Nov., 1901.

implied that he regarded the act as a justifiable one, he did not claim that it was not a crime on his part as paranoiacs usually do, nor did he in any way indicate that he regarded himself a victim of conspiracy or persecution. On the contrary, he declared—to the people's experts—that he fully understood what he did when he shot the President and was willing to take the consequences; that "I know what will happen to me—if the President dies, I will be hung." Justice White, commenting on Czolgosz's plea of "guilty" when arraigned for trial—a plea which could not be accepted under the law—said: "The prisoner's plea of guilty indicates that he himself anticipates no escape from the penalty which the law prescribes for a crime of the character alleged in the indictment." Again Czolgosz said: "I done my duty, I don't believe in voting; it is against my principles. I am an Anarchist." He further said that he had been an ardent student of the doctrine of Anarchy and had attended many "circles" where these subjects were discussed. He had attended a meeting of Anarchists about six weeks ago and also in July; had met and talked with an Anarchist in Chicago about ten days ago; that he belonged to a "circle" in Cleveland which had no name. "They called themselves Anarchists." That he went to Cleveland "on no particular business" the Friday before the assassination. He had been in Buffalo for two or three weeks prior to going to Cleveland. "I planned to kill the President three or four days ago, after I came to Buffalo"—from Cleveland. "I don't believe in the republican form of government and I don't believe we should have any rulers. I had that idea when I shot the President and that is why I was there."

In explanation of his abandonment of his religious faith and his rejection of the services of a priest, Czolgosz said the night before his execution: "I would like the American people to know that I had no use for priests. My family are all Catholics and used to go to church until the hard times of 1893. We had been taught by the priests that if we would pray, God would help us along, but it did no good; it didn't help us and we stopped going to church at that time." He also said at this interview: "McKinley was going around the country shouting prosperity when there was no prosperity for the poor man. I am not afraid to die. We all have to die sometime."

It may be said that Czolgosz' belief which he expressed as he went to his death, that the President "was an enemy of the good working people," was a delusion, and such it undoubtedly was in the broadest sense of that term; that is, it was a false belief, but it was in no sense an insane delusion or false belief due to disease of the brain. On the contrary, it was a political delusion, so to speak—a false belief founded on ignorance, faulty education and warped—not diseased—reason and judgment—the false belief which dominates the politico-social sect to which he belonged and of which he was a zealot, who in common with his kind believes that all forms of government are wrong and unnecessary—a body of malcontents whose teachings oppose all government and who advocate the use of violence to destroy the existing social and civil order of things. By his own admissions, Czolgosz was a devout Anarchist and a firm believer in the principles of "Free Society," as taught by Emma Goldman—of whom he was an ardent admirer—and others. These were the beliefs which furnished the motives for the murderous deed.

That Czolgosz was an Anarchist and actuated in his crime by the motives which spring from the teachings of that sect, are clearly shown by: (1) His declarations after his arrest, namely, that he did not believe in any form of government or law and that all rulers were tyrants who ought to be put down. (2) His admissions to the District Attorney that he was a member of Anarchistic societies or circles and had frequently attended the meetings of the same; also that he had been influenced in his views by the "lectures" of Emma Goldman; and that when apprehended Anarchistic literature was found on his person, and (3) the recognition and commendation which he has received at the hands of Anarchists at their meetings both in this country and abroad since his death, several of these societies having openly recognized him as such and lauded his action.

The Anarchists' creed teaches that when one of their number is selected to do a certain deed, he is to proceed about it quietly and in his own way, taking no one into his confidence; that, having accomplished the deed, if apprehended, he shall not admit his connection with any other members of the circle; that, if convicted and sentenced to die he shall go to his death without revealing his connection with others, resting secure in the belief that he will be ever regarded by his associates as a martyr and a hero who died in the discharge of a noble duty. The course and conduct of Czolgosz from the beginning down to his death are entirely in keeping with this creed. And, finally, the cool and courageous manner in which he met his death, and the fact that, from the day of his arrest until he died, he never uttered a word that could be used against his accomplices—if he had any—and that he died—as Anarchists who suffer the death penalty always die—without uttering a word that would tend to incriminate any of his coconspirators, tend to stamp him as an Anarchist.

In conclusion, the writer, having viewed the case in all its aspects, with due regard to the bearing and significance of every fact and circumstance relative thereto that was accessible to him, records his opinion unqualifiedly that Leon F. Czolgosz on September 6, 1901, when he assassinated President McKinley, was in all respects a sane man—both legally and medically—and fully responsible for his act.

THE POSTMORTEM EXAMINATION OF LEON F. CZOLGOSZ,

BY EDWARD ANTHONY SPITZKA, M.D.
OF NEW YORK.

THE postmortem examination was performed by the writer under the supervision of Dr. Carlos F. Macdonald of New York, who was requested by the State Superintendent of Prisons to take medical charge of the execution in conjunction with Dr. John Gerin, Prison Physician. The examination began at 7:50 a. m. and was completed at 12:30 p. m. Among the witnesses were the physicians in attendance at the execution.

As the body lay upon the table in the dorsal position, the right leg, to which the electrode had been attached, was slightly flexed and a trifle abducted. This attitude of the body has been found to be uniform in the postmortem examinations made on many other electrocuted criminals by Dr. Ira Van Gieson.[1] In all of these cases the electrode had been applied to the knee flexure.

Corresponding to the attachment of the leg-electrode there was a superficial blistering, with some desquamation of the epidermis and some edema. At the site of application of the head-electrode there were only a few signs of vesication limited to the occiput.

Postmortem discolorations existed in all the extremities, but not in the trunk, head or neck, where the skin was fairly white. There was postmortem lividity

of the toe and finger nails. The pressure of the straps had not produced any discolorations. There was a discharge from the urethra of small amount, probably seminal fluid.

The assassin's physiognomy may be described as youthful and with rather a pleasant expression. The nose is pointed, slightly retroussé and fairly straight, deviating a little at the point of the injury inflicted at the time of the assassination. The eyes are blue, the pupils equal and moderately dilated. The hair is a light brown and slightly curly. The face is oval and symmetrical. The ears are well formed and absolutely symmetrical. The mouth is well-shaped, the lips full; measuring the true orifice, the width is 4 cm., between the outer angles 5 cm. The teeth are of normal shape, but are in poor condition. The external genitals are normal and are unclean with accretions of smegma under the prepuce. There are two flat cicatrices, one 4 mm. in diameter, the other half that size, on the mu-

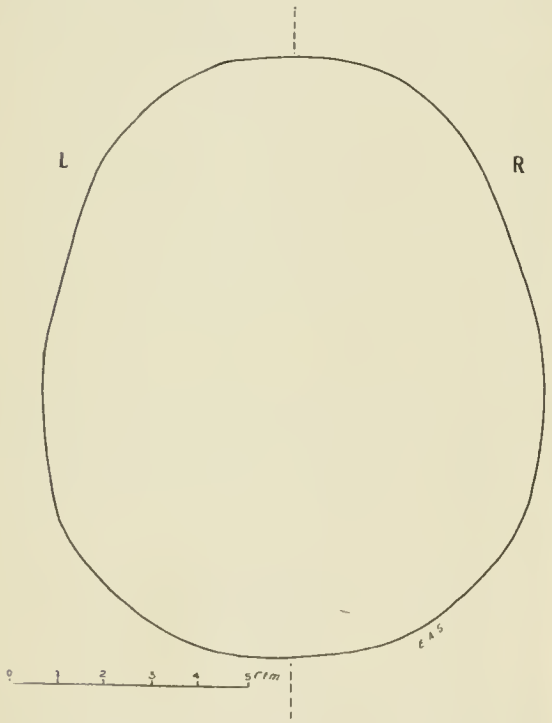

Fig. 5. Horizontal outline of the head (by lead-strap).

cous surface of the prepuce about 5 mm. from the corona glandis. The tissues under and about these cicatrices are not indurated, and the scars are doubtlessly the remains of chancroids acquired at some time previous. As stated before there has been a discharge of seminal (?) fluid, some of which is still within the urethral passage.

At 8:10 a. m. the surface temperature of the body taken on the side of the chest with a "Seguin" surface-thermometer was 97° F.; per oram 97.4° F. The body cooled very slowly throughout the examination, and the greatest amount of heat appeared to be retained in the brain. Rigor mortis set in about three hours after death.

The following measurements of the head were recorded:

	Centimeters.
Maximum circumference (21½ inches)	54.6
Maximum antero-posterior diameter (from glabella to maximum posterior point)	18.7
Maximum lateral diameter	15.5
(Cephalic Index—82.88)	
Bi-auricular diameter (between roots of zygomæ)	15.0
Length of face (from the inter-superciliary point to the superior alveolar point between the middle incisors)	9.2
Bi-zygomatic diameter	14.5
Minimum frontal diameter	12.0
Diameter from glabella to inion	19.1
From vertex to hair-line	12.0
" hair-line to root of nose	6.0
" root of nose to its base	5.3
" base of nose to chin	7.0
Vertex to chin (diameter)	25.4
Breadth between pupils of eyes	6.8
Breadth of nose at its base	3.4
Width of mouth (internally)	4.0
" " " (externally)	5.0
Length of ears (both sides equal)	6.1

Fig. 9. Cast of Head.

After these measurements had been taken, about fifty minutes were devoted to the making of plaster-moulds of the entire head.

Fig. 10. Cast of Head.

A cast has since been made from these moulds and two photographic views, in full face and in profile, are

presented here. Unfortunately the left ear in the mould had been broken during the transportation from Auburn, and the fragments were pieced together with difficulty. The defects have been rectified in the photograph. On the subject the ears were perfectly symmetrical, both as to form and size.

The moulds were made upon the head while the body lay prostrate upon the table. This attitude gave rise to the prominence of the "Adam's apple," and to the slight parting of the lips. The hair was rubbed well with vaseline and flattened as much as possible to prevent the plaster from adhering.

On the skull the following measurements were taken: Max. antero-posterior diam., 18.0 cm. Max. lateral diam., 14.7 cm. Cranial Index, 81.66.

The head of Czolgosz, as is typical of the Poles, falls into the sub-brachycephalic class; according to Weisbach the cephalic index of forty Poles was 82.9; 82.88 in Czolgosz.

At the time of Czolgosz's reception at the Auburn State Prison (Sept. 27th) measurements of his body were taken according to the Bertillon system by J. N. Ross. I reproduce here the more important figures.

Stature (5 ft., 7½ in.)	171.4	centimeters
Stretch	181.0	"
Trunk	91.1	"
Head, length	18.6	"
Head, width	15.6	"
Cheek, width	14.5	"
R. ear, length	6.3	"
L. foot	26.0	"
L. mid. f	11.7	"
L. lit. f	9.0	"
L. cubit	47.2	"

"These measurements are all medium and each is consistent with the others. The stretch and cubit measurements might be said to be slightly out of proportion, indicating that his forearms were slightly longer than those of a majority of men of his stature, but this excess of length is not sufficient to call for comment." His weight on that day was 141 pounds.

The marks and scars are here reproduced in the order in which they appear on the Prison's Department's identification card.

"I. Sev. sm. cics. post. first fgr. left hand near 2d jt.

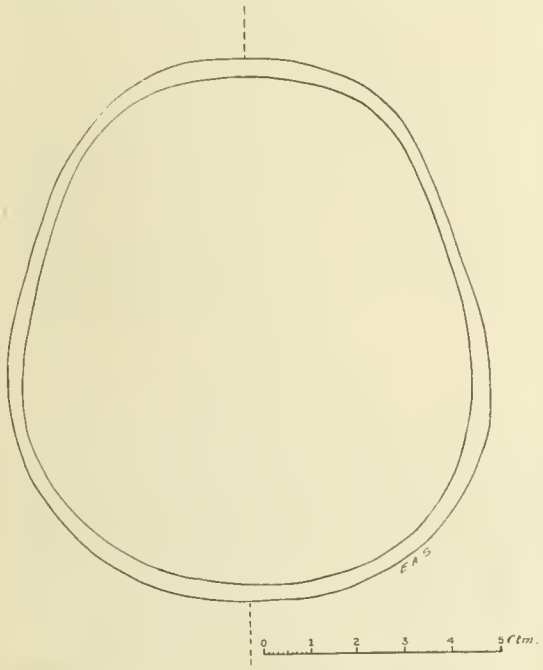

Fig. 7. Outline drawing of the skull in the plane of the saw-cut described in the text, showing thickness of bones.

Cic. of 1 ob. ex. on 1st phal. 3rd fgr. left hand post.

"II. Cic. of 3 rec. ver. crossing 3rd joint, mid. fgr. right post. Cic. of 1 circ. at 5 over right wrist post.

"III. Mole at 5 under left cheek bone and 9 to left med. line.

"IV. Sev. moles on front and back of neck."

Next the cranium was opened and the brain removed. The scalp was divided by means of a median incision passing from the glabella to the inion. On incising the scalp a quantity of dark fluid blood escaped. The scalp was of moderate thickness, firm and well adherent to the skull. The two flaps of the scalp were dissected from the skull and drawn down on either side of the head. The sutures were well-marked and no synostosis was observed. Supernumerary or abnormally-developed bones were not discernible.

The calva was removed by a saw-cut passing around the cranium about 1.5 cm. above the glabella and about 2.5 cm. above the inion. In Fig. 7 is shown the outline of the thickness of skull along this section. In the removal of the calva, the saw was supplemented by the chisel and hammer. The calva came off readily, the dura being non-adherent. There was no marked escape of cerebrospinal fluid. Along the saw-cut the skull was slightly flatter in the fronto-parietal region on the right side, while it was more curved or rounded on the left. The right parieto-occipital region was a trifle fuller than on the left side. The markings on the internal surface of the calva, such as the groove for the superior longitudinal sinus and for the meningeal vessels, the digitations, and the impressions for the Pacchionian bodies, etc., were all distinctly marked. The dura was grayish-white, moderately translucent and somewhat dry; there existed a marked engorgement of dark fluid blood. The dura was neither tense nor loosened. The Pacchionian bodies were of the usual number and distribution. The inner surface of the dura was fairly moist. There were no evidences of hemorrhagic pigmentation or of pachymeningitis.

The brain, invested by the pia-arachnoid, was exposed by crucial incisions into the dura, which was perfectly non-adherent to the membranes within. The brain was carefully removed and during most of the subsequent examination was kept in a salt-solution (about 1 part in 20 of water). At the time of removal, still invested by the pia-arachnoid, and with the ventricles unopened, the entire brain weighed fifty-one and a half ounces avoirdupois (1,460 grammes).

The base of the skull was normal in every respect. The pia-arachnoid was of normal thinness, and devoid of opacities or other signs of disease—past or present. The only unusual appearance was an injection of bright red blood in the finer vessels of the pia, due, if we may judge from previous reports of autopsies on electrocuted criminals, to the high electro-motive force exerted by the fatal current in this part of the body. The pia was stripped off with ease, being nowhere adherent to the cortex.

Examination of the Brain.

(See Figures 1, 2, 3 and 4.)

In general the brain presents no marked peculiarities of shape or size. It is firm to the touch and no portion of it despite most careful examination feels softened or indurated.

The brain was divided into its natural segments according to the following method: The ectal border of the optic tract and the tænia thalami ("ripa" of Wilder) are used as guides for a single simple incision: those of either side converge cephalad to meet in front of the chiasm; the usual cut through the callosum and the terma (lamina terminalis) completes a tri-section

which leaves the cerebrum (prosencephal) and brain-axis separated as nearly the ideal as can be. This mode of dissection is a modification of Meynert's plan and is a method by which each hemicerebrum, with the insula intact, is separated from the brain-stem; whereas Meynert, by trenching round the circuminsular boun-

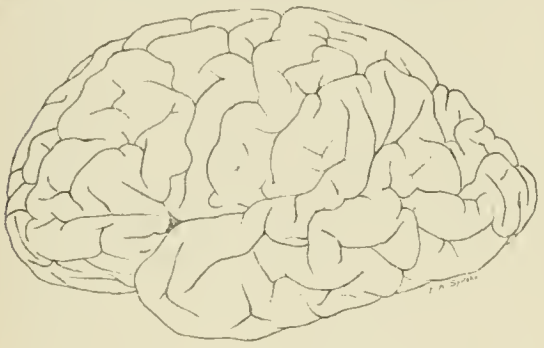

Fig. 1. Lateral view of left hemicerebrum.

daries separates the convex cortical mass from the brain-stem plus the insula, leaving a cortical component attached to the axial structures. The Meynert method consequently does not give the weight of the cerebral hemispheres strictly speaking. As far as the caudatum and lenticularis are concerned this would not be a serious objection; but as it also excludes the important cortical area of the insula—no inconsiderable portion of the cerebral projecting and associating tracts—it falls short of the method adopted here.

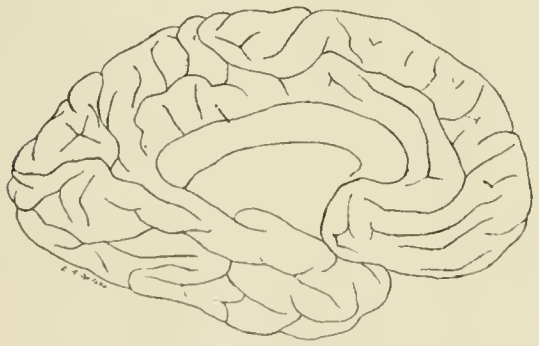

Fig. 2. Mesial view of the left hemicerebrum.

After the brain had been thus dissected and drained, and the pia-arachnoid stripped off the cerebrum, the segments were found to have the following weights:

Left hemicerebrum (without pia)	585 grams.
Right hemicerebrum (without pia)	600 "
Cerebellum (with pia-arachnoid)	166 "
Isthmus (" " ")	64 "
	1,415 grams.

Examination of the paracœles (lateral ventricles) in both hemicerebra revealed the veins of the striatum (the striatal veins) injected with deep violet-colored blood. The cornua were of normal extent and conformation throughout. The endyma was smooth, the choroid plexus was normal and contained little blood; the velum interpositum ("velum" of Wilder) was normal.

Left Hemicerebrum.

The sylvian fissure is 6½ cm. in length; the episylvian, 2¼ cm.; the hyposylvian is absent. The presylvian ramus is 2 cm. in length, the subsylvian 1 cm. in length.

The central fissure is fairly flexuous and ramified; it is uninterrupted throughout its length and is separated from the sylvian by a narrow isthmus. At its ventral end the fissure terminates in a hook-like manner. The dorsal end appears on the mesial surface. The super-central fissure is confluent with the superfrontal, but is separated from the precentral. The superfrontal is distinct in the mid and postfrontal regions, but is absent in the prefrontal region. The three-tier type is preserved in the prefrontal region by the existence of a medifrontal fissural segment about 4 cm. in length, and which is confluent with the orbitofrontal. This is not very clearly seen in the figure, owing to the effect of the convexity. The reader is referred to the schematic outline in Fig. 8.

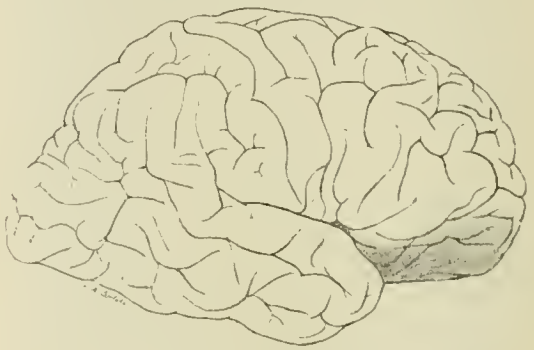

Fig. 3. Lateral view of the right hemicerebrum.

The precentral fissure is confluent with a small diagonal fissure, and this in turn with the presylvian. It sends an "anterior precentral ramus" across the medifrontal gyrus to anastomose with the superfrontal fissure.

The subfrontal fissure is independent and sends off several rami into the neighboring gyres. There is a very long radiate fissure.

The precentral gyrus is not very broad as compared with the postcentral. The three frontal gyres are fairly massive and marked by fissures which run generally transverse.

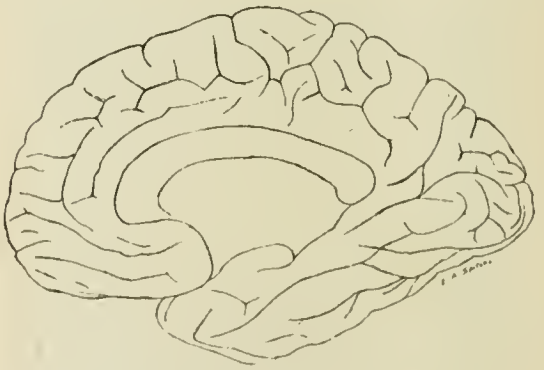

Fig. 4. Mesial view of the right hemicerebrum.

The postcentral fissural complex consists of three segments. The dorsal one is very flexuous and ramified, but independent. The middle segment is confluent with the parietal, and is only superficially joined to the third segment, the subcentral. The transpostcentral is hardly visible on the external surface, but on examination is found to communicate with the circuminsular fissure.

The parietal fissure is notable for the angle which it makes with the intercerebral cleft, converging rapidly toward it as it passes caudad. It communicates with the paroccipital fissure over a vadum about 6 mm. in

depth. Otherwise the paroccipital does not communicate with any other fissure. There are two transparietal fissures; the cephalic one communicating with the precuneal fissure on the mesial surface.

The temporal lobe is of good size and shape. The supertemporal fissure is uninterrupted throughout its length and communicates with the intermedial over a slight vadum. The meditemporal fissure is represented by four segments. Numerous fissures, the "lateral occipital" among them, mark the region of the occipito-temporal transition. The postcalcarine fissure appears on the lateral surface for about 2 cm.

The postcentral gyrus is of good development and is fairly wide. The marginal, angular and post-parietal gyral portions of the sub-parietal lobule exhibit a moderate development. The parietal gyrus is of cuneiform shape, broad cephalad, narrow caudad. The supertemporal gyrus is very sinuous. The remaining temporal gyres are fairly wide and well developed.

The subcalcarine gyrus is wide in its caudal portion. The cuneus is small, rather unusually so. The precuneus is of good size and conformation. The paracentral gyrus is of typical appearance and of the usual size. It is traversed by a well-marked inflected fissure and by a tri-radiate intraparacentral fissure. The mesial surface of the superfrontal gyrus is of moderate size and is marked by five or six transverse fissures, three of which are rami of the supercallosal. The callosal gyrus in its cephalic half is doubled by a long fissure running parallel with the supercallosal; in its caudal part it is traversed by several transverse fissures.

There are two well-marked rostral fissures (rostral and subrostral) and a short transrostral. The supercallosal fissure is long and anastomoses with the paracentral over a vadum of 5 mm. The paracentral fissure in turn anastomoses with the precuneal over a vadum of 3 mm. The occipital and calcarine fissures

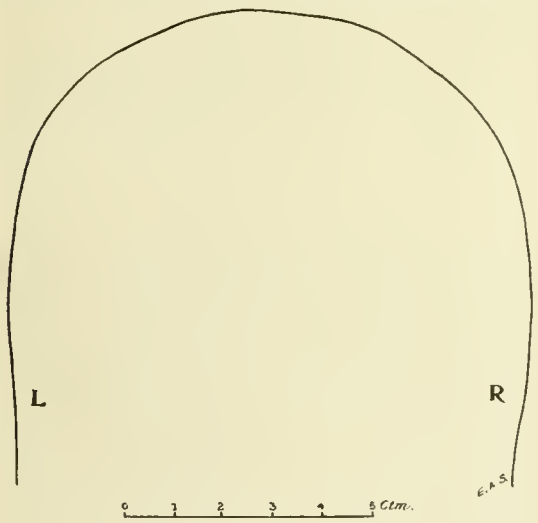

Fig. 6. Outline of the vertex from ear to ear (taken just in front of the roots of the zygomæ).

anastomose freely. A "posterior cuneolingual" subgyrus tends to partially separate the calcarine from the postcalcarine. The collateral fissure is fairly well ramified. The insula exhibits a good development. There are six gyres proper, with seven peri-insular digitations. The insula was completely covered by the opercula.

Right Hemicerebrum.

The sylvian fissure is 5½ cm. in length; the episylvian 3 cm.; the hyposylvian 1½ cm.; the presylvian 2½ cm.; the subsylvian is very short.

The central fissure is uninterrupted throughout its length, and is separated from the sylvian by a very narrow isthmus. Its dorsal end crosses the dorsi-mesal margin. The supercentral fissure anastomoses with a long superfrontal fissure, but not with the precentral.

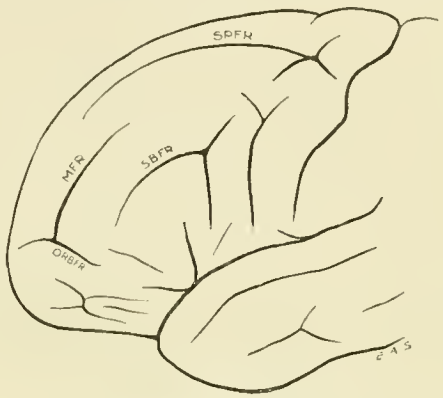

Fig. 8. Diagrammatic sketch, showing disposition of the fissures and gyral tiers in the left frontal lobe.

The precentral fissure joins both the transprecentral and the diagonal, and by means of these the sylvian cleft.* This fissure gives off an "anterior precentral ramus" from which springs the caudal segment of the subfrontal fissure.

The superfrontal fissure is long and uninterrupted, extending nearly to the frontal pole. There is no true medifrontal fissure present. The subfrontal fissure is in two segments, the caudal segment being confluent with the precentral by means of its "anterior ramus"; the cephalic segment anastomoses with the orbito-frontal. Besides an independent radiate fissure there are other unnamed fissures in the subfrontal region. There are two long sagittally directed orbital fissures; the lateral one of these communicates with the orbito-frontal.

As in the left half, the precentral gyrus is rather narrow as compared with the broader postcentral gyrus. The three frontal gyres are all of good width and are chiefly marked by transverse fissures. The postcentral fissural complex is made up of two segments superficially confluent with each other. The dorsal segment is short. The ventral segment is longer, and is confluent with the parietal fissure. The parietal fissure is uninterrupted, deep, and separated from the paroccipital fissure by an isthmus. There is a well-marked post-paroccipital fissure and one distinct transparietal.

The supertemporal fissure is long, uninterrupted, and not deeply confluent with any other fissure. There are four meditemporal fissural segments. The intermedial joins the parietal. There is a fairly well-marked "lateral occipital" fissure.

The postcentral gyrus is fairly wide and flexuous. The parietal gyrus is wide, and exhibits the same cuneiform shape as described for the left side. Of the subparietal gyres the angular gyrus is of fair size, while the remainder of this territory shows only a moderate development. The paroccipital gyrus is very small, but quite flush with the general surface of the brain.

The gyres of the temporal lobe show very good development, and in the occipito-temporal transition the markings are quite complex.

On the mesial surface the supercallosal fissure consists of two segments, and there is a similar duplica-

*Found by Sernoff in 44 per cent. of Polish brains.

tion of the callosal gyrus (in its cephalic portion) as has been described in the left half. A notable peculiarity consists in the confluence of the inflected fissure with the paracentral stem, while the cephalic paracentral limb is separated from its stem, but is joined to the caudal end of the supercallosal. There is a tri-radiate intraparacentral. The precuneal fissure would be independent but for a superficial junction with the paracentral.

The occipital fissure is deeply confluent with the calcarine. The postcalcarine is tri-radiate and separated from the calcarine by a "posterior cuneo-lingual" isthmus.

The superfrontal gyrus is fairly well-marked by many transverse fissures, and by two long and distinct rostral (rostral and subrostral) fissures. The precuneus is large, a little larger than its fellow on the left side. The cuneus is as small as on the left half. The subcalcarine gyrus is of considerable width in its caudal portion.

The insula presents an ordinary degree of development, and, as on the left side, possesses six gyres, with seven peri-insular digitations.

Section of the Brain.

In cutting the brain, the resistance to the knife suggested neither increased nor diminished consistence. The cut surface was moderately moist, the gray as well as the white matter was of normal color, the cortex was of the usual thickness, and there existed neither anemia nor hyperemia. No hemorrhages, sclerotic patches, neoplasms or other lesions were discoverable.

The basal ganglia, crura, cerebellum, pons and oblongata were all perfectly normal, there being even an absence—so far as naked-eye examination could determine—of the small hemorrhages in the floor of the fourth ventricle, which have been usually found in electrocuted criminals.[2]

The spinal cord was not examined.

Examination of the Thorax and Abdomen.

An incision was made from the top of the sternum to the pubic symphysis, a quantity of dark fluid blood escaping. The diaphragm was found attached to the sixth rib on both sides of the sternum. About three to four fluid-drams of clear fluid were found in the pericardial sac. The heart was firm and appeared to be in a tetanized condition; it had ceased in systole. This contracted condition is doubtlessly due to the high electro-motive force of the current. The ventricles were empty; the heart-walls, endocardium and valves were normal. The weight of the heart was eleven ounces. Both lungs were somewhat emphysematous, floating a trifle more than half out of water. They were moderately pigmented and of firm consistency. None of the bronchial lymph-nodes were enlarged. Except for a few bands of pleuritic adhesions of the right lower lobe, there were no lesions in either lung. The left lung weighed 7¾ ounces, the right lung 8½ ounces.

The larynx, aorta, and the venæ cavæ were normal. The stomach was in the normal position, well contracted, and well under the diaphragm, with only a small residue of food near the pyloric end—the prisoner having had nothing to eat since the evening before the execution.*

The examination of the intestines was a brief one, as nothing unusual was seen. The appendix was 8 cm. in length, free, and lay dorsad and mesad of the cecum.

The pancreas was normal. The liver was dark, hyperemic, but healthy; there were no patches, infarctions or other lesions. The gall-bladder contained about one ounce of clear bile. The liver weighed 61 ounces. The spleen was also hyperemic, mottled with light pink streaks, but of normal structure. Weight, 7⅜ oz. The kidneys were moderately supplied with fat, markedly hyperemic, but all the structures could be made out clearly to be of normal condition. The left kidney was somewhat larger than usual. The capsule was non-adherent in both instances. The left kidney weighed 7¼ ounces; the right weighed 5¼ ounces. The bladder was somewhat contracted, firm, and contained about three ounces of clear urine. The bladder-wall and mucous membrane were normal in all respects. The prostate was rather firm but not enlarged. The urethra, testes, etc., were normal.

It had been the writer's purpose to make a fuller anatomic and anthropometric investigation upon the assassin, but the peculiar circumstances which arose in the matter of the disposal of the body, and the anxiety of the prison's warden to put the body under earth, forced me to conclude my researches after having obtained the most essential data for purposes of record and future study.

The results of the necropsy can be summed up by saying that Czolgosz was in excellent health at the time of his death. There was, of course, a marked condition of hyperemia of all the viscera, and the blood was considerably altered in that it remained fluid, doubtless due to the destruction of the fibrin-ferment, or of the fibrinogen, or both. These phenomena, as also the tetanized condition of the heart, have been observed by E. C. Spitzka, Carlos F. MacDonald, Van Gieson and E. W. Holmes[3] on criminals executed by lethal currents of electricity.

The external appearances of the body of the assassin, especially the facial expression, have been admirably described by Murat Halstead, who happened to be present, in a short but vivid account of the autopsy, entitled "Czolgosz after Death."

"The spectacle was interesting; the assassin had been dead but a few minutes, and was lying at full length on his back on the table provided for the surgeons, his body white as marble, his face not at all distorted. One might say he was as if sleeping, but that would not describe the expression of the features, though that was almost of perfect repose. The head rested on the back part of the table so as to elevate the chin and allow the forehead to slope downward. There was no sign of a great agony; the hair had not been removed for the electrode, but was full of water from the sponge, and in disorder. If there was any mark on the head made by the deadly shock it was not visible. There was a red blotch on the right leg below the knee. . . . The strong throat, with a distinct Adam's apple, was prominent. The lips were slightly parted with more than the curl they had in life. . . . There was nothing in the appearance of the body of the emaciation from imprisonment so often referred to. Any physician would say the corpse was that of a well-nourished young man. The figure was of good proportions, his limbs especially so. The arms were not muscular. Evidently he was not a man who had cultivated his muscles by exercise or expanded or hardened them by labor. The arms were of a young man of leisure—smooth, round and fair. His hands were not in any way notable. He had high insteps, neat ankles and long toes. The muscles of the legs were better developed than those of his arms, indicating he was swift of foot. He was not noticeably spare in body; his chest was round and symmetrical—not lean—but the ribs quite distinct. With his head thrown back, it seemed to have been well poised in life, more so than

*The "hearty breakfast" so graphically described in most newspapers was but a figment of the imagination.

is shown in his pictures—all of which that are familiar having been taken in prison. Nothing in his face or his person gave indication of heavy feeding or drinking, or of evil indulgence. There were none of the inevitable traces of confirmed dissipation."

The question as to whether his body invested a healthy mind opens up a wide topic for discussion which it is not entirely in the writer's province to pursue. So far as our knowledge of the correlation of brain-structure and brain-function extends, nothing has been found in the brain of this assassin that would condone his crime for the reason of mental disease due to intrinsic cerebral defect or distortion. The brain-weight, though by itself unimportant, when considered in its other relations points to a good condition of the organ. Divested of its membranes, dissected, drained and after being immersed in a salt solution for several hours, its weight was 1415 grams, a trifle less than fifty ounces. This weight is even a little over the average. Giltschenko[4] records observations upon the weight of 102 Polish brains, the average being, for males, 1397.8 grams, with an average stature of 168.12 cm. The development of the fissures and gyres, from a morphological view-point, has taken place in the direction usual in ordinary average brains. There are no marked evidences of arrested development or of pithecoidal anomalies.* Generally speaking, this brain does not exhibit that especial kind of asymmetry of gyral structure in the cerebral halves that is so characteristic of the brains of highly endowed individuals. There are many features in the one hemisphere that are reproduced almost exactly alike in the other. The few peculiarities encountered in the course of the fissures, such as the confluence of the left precentral, by its anterior ramus, with the superfrontal—across the medifrontal gyrus; or the separation of the right cephalic paracentral limb from its stem, while at the same time the inflected joins the paracentral (a feature found by the writer in 9 out of 160 hemicerebra in which the inflected was present[5] and also the smallness of the cuneus—are insignificant so far as individual brains are concerned, and will be discussed at length in a later contribution.[6]

The skull is not symmetrical, but the asymmetry is slight and fully within the normal range of variation. An absolutely symmetrical skull probably does not exist.

It is a probable fact that certain oft-mentioned aberrations from the normal standard of brain-structure are commonly encountered in some criminal or degraded classes of society, and those who have attempted to found a school of degeneracy have endeavored to explain crime and social wickedness as due to "accidental persistence of lower types of human organization." But these structural anomalies, so far as they have been described in the brains of criminals, are too few and too insufficiently corroborated to warrant us in drawing conclusions from them. Various perversions or anomalies of mind may exist in this class without presenting a uniform criminal type, either from the sociological or the anatomical aspect. Of course, it is far more difficult—and it is impossible in some cases—to establish sanity upon the results of an examination of the brain than it is to prove insanity. It is well known that some forms of psychosis have absolutely no ascertainable anatomical basis; and the assumption has been made that these psychoses depend rather upon circulatory and chemical disturbances. So far as this question touches upon the brain and body of Czolgosz, there have been found absolutely none of those conditions of any of the viscera that could have been at the bottom of any mental derangement. Taking all in all, the verdict must be "socially diseased and perverted, but not mentally diseased." The most horrible violations of human law cannot always be condoned by the plea of insanity. "The wild beast slumbers in us all. It is not always necessary to invoke insanity to explain its awakening."

In conclusion, the writer wishes to express to Dr. Carlos F. MacDonald his appreciation of and thanks for the exceptional opportunity afforded in the performance of this autopsy.

66 East 73d Street.

*The reader who may have happened to see an article entitled "Degeneracy and Political Assassination," by Eugene S. Talbot, M.D., D.D.S., in "Medicine," December, 1901, must be surprised to find that the citation of "It is admitted by E. A. Spitzka that the brain presented anomalies" is directly contradicted here. This is one of those numerous instances showing the desirability of medical writers awaiting the responsible publications of scientific results or conclusions, instead of giving newspaper canards currency by incorporating them in their papers, and at the same time distorting facts to fit the theories they hold. The paper of Dr. Talbot presents such an endless vista of degeneracy as to give ground for apprehension that many other facts on which it rests were obtained in a similarly uncritical way and, hence, have misled that writer as unfortunately as in the Czolgosz matter.

The incorrect and misrepresenting citation were sufficiently trying without additional infliction in the way of an invidious implication, be it ever so unintentional on Dr. Talbot's part; but when the entire tone of the article in reference to the Czolgosz trial is critical anent its alleged "cooked and dried" character, and he intimates suppression of postmortem evidences, it sounds as if "It is admitted by E. A. Spitzka that the brain presented anomalies" indicated an unwilling admission and, hence, a partisan spirit. However, as the statement is altogether false, this feature needs no more consideration than "No microscopic examination worthy of the name was made."

We deserve at least this piece of justice that we did not pretend to have done anything we did not do. Had we made one, it would have been our aim to have been more accurate in citation of collateral writers than Dr. Talbot has been or seems to have aimed at being. So how it can have been worthy or unworthy of any name, I cannot see.

Dr. Talbot, not familiar with the law of New York State, is in error when he says: "The course of the court in refusing to accept his plea of guilty and forcing him to accept counsel is justifiable only on the ground of assumed insanity." In this State, a plea of guilty is inadmissable by law in capital offences.

A REPORT OF FORTY-FIVE UNPUBLISHED CASES OF HEMORRHAGE TREATED BY THE INTERNAL ADMINISTRATION OF THE SUPRARENAL CAPSULE.

BY SAMUEL FLOERSHEIM, M.D.,

OF NEW YORK.

THE internal administration of the suprarenal substance has been employed with distinct success by a few observers in hemorrhages resulting from various causes. The author[1] reported sixteen cases of hemoptysis from various causes successfully treated by the internal administration of the suprarenal powder. Wm. B. Kenworth[2] reported fourteen additional cases. F. A. Mandeville[3] treated a case of epistaxis by the internal administration of the suprarenal sub-

stance. James B. Moore[4] also treated a case of hemoptysis with the suprarenal powder. Cases of uterine hemorrhage successfully treated by the administration of the suprarenal extract have been published by George Tucker Harrison,[5] F. Churchill,[6] James B. Moore and by the author.[7]

The author[8] reported two cases of hematuria successfully treated by the internal administration of the suprarenal powder. Francis J. Quinlan[9] reported a case of hemorrhage from the stomach successfully treated by the same means. Stephen F. Sturdevant[10] reported excellent results in a case of accidental abortion of three and a half months which resisted most other remedies. O. F. F. Grünbaum[11] reported that hematemesis had been controlled by small doses frequently repeated. L. Emmett Holt reported to the American Pediatric Society at Buffalo, 1901, a case of gastro-intestinal hemorrhage in a newly-born infant successfully treated by the suprarenal extract. Twelve grains were administered by mouth in twenty-four hours. Victor C. Vaughn reported at the St. Paul meeting of the American Medical Association, 1901, a case of intestinal hemorrhage in a woman successfully treated by the internal administration of the extract.

I know of no other remedy whose internal administration has given me such prompt results. In my hands it has proved a safe remedy, even when the hemorrhage was complicated by diseases of the heart, lung, kidney, etc.

The suprarenal powder, five grains, when placed on the tongue, thoroughly rinsed with the saliva and swallowed without water usually produces an effect within ten minutes. Nausea and vomiting have been observed in a few cases when the suprarenal powder was administered.

Twenty-one Cases of Hemoptysis.

Case I.—Mrs. H., aged thirty-six years, had a mitral regurgitant murmur and was very anemic. She was attacked with hemoptysis which nitroglycerin failed to benefit and digitalis and ergot increased. The suprarenal substance was administered and a prompt and marked decrease in the hemorrhage was noted. The pulse became stronger and softer. The dose was repeated every six hours. No return of the hemorrhage was observed six weeks later.

Case II.—Mrs. A. R., aged fifty-one years, had mitral regurgitation and aortic stenosis. She suffered from repeated attacks of dizziness and dyspnea. During an attack of hemoptysis the remedies administered in Case I. were followed by no relief. The suprarenal powder was administered and the hemorrhage promptly ceased, the pulse was strengthened and the dyspnea relieved. The dose was repeated every four hours. No return of the hemorrhage was observed fifteen days later.

Case III.—Mr. E. D., aged thirty-one years, single, had a loud mitral regurgitant murmur. An attack of hemoptysis, due to overexertion, was not benefited by the use of the ordinary remedies. The suprarenal extract was administered and a marked lessening of the hemorrhage occurred within ten minutes. The hemorrhage was soon completely checked. No return of the hemorrhage was observed three weeks later.

Case IV.—Mr. J. W., aged twenty-one years, single, had mitral regurgitation and pulmonary tuberculosis. He was very anemic and he had had many attacks of syncope. Frequent attacks of hemoptysis were only slightly benefited by the ordinary remedies. There was always some blood in his sputa. The administration of the suprarenal powder during a severe exacerbation of the hemoptysis markedly decreased within ten minutes and completely checked the hemorrhage in two hours. The dose was repeated every two to four hours. No return of the hemorrhage was noted three months later.

Case V.—Mr. D. C., aged twenty-five years, married, had mitral regurgitation and pulmonary tuberculosis. His case was similar to Case IV. The same beneficial effects were also observed. No return of the hemorrhage was observed three weeks later.

Case VI.—Mr. C. G., aged thirty-seven years, married, had a very loud mitral regurgitant murmur. He also had pulmonary tuberculosis. The ordinary remedies had but little effect on the hemoptysis. When the suprarenal powder was administered, a prompt, complete and permanent checking of the hemorrhage resulted. No return of the hemorrhage was observed two months later.

Case VII.—Mr. J. C., aged thirty-nine years, had pulmonary and laryngeal tuberculosis. The suprarenal powder was administered during an attack of hemoptysis and a prompt checking of the hemorrhage resulted. The pulse became strong and regular. The doses were administered at five-hour intervals and no return of the hemorrhage was observed two months later.

Case VIII.—Mr. J. L., aged twenty-nine years, married, had pulmonary tuberculosis. He had a slight attack of hemoptysis which was promptly and permanently controlled by three doses of the suprarenal extract at four-hour intervals.

Case IX.—Mr. D. L., aged thirty-six years, single, had pulmonary tuberculosis. He was weak and his pulse was bad. A mild attack of hemoptysis, which ergot and digitalis increased, was promptly checked by the suprarenal powder. The pulse became fuller and regular and the cough was lessened.

Case X.—Mr. J. R., aged twenty-nine years, married, had pulmonary tuberculosis. Several attacks of hemorrhage which were with difficulty controlled by the ordinary remedies, were promptly checked by the suprarenal substance.

Case XI.—Mr. K., aged thirty-four years, had frequent attacks of hemoptysis. No cause was discoverable. Ergot, which usually benefited, failed to decrease the hemorrhage. Suprarenal powder was administered resulting in a prompt decrease in the hemorrhage and in two days it was completely checked.

Case XII.—Mrs. H., aged forty-one years, had

pulmonary tuberculosis. An attack of hemoptysis was promptly checked by the suprarenal extract. Slight recurrences were also checked by the suprarenal powder.

Case XIII.—Mrs. M. H., aged twenty-nine years, had pulmonary tuberculosis and a severe attack of bronchitis. Six weeks of constant coughing eventually resulted in producing a severe attack of hemoptysis. The usual remedies given for a day failed to diminish the hemorrhage. The administration of the suprarenal powder was followed by a rapid decrease in the hemorrhage and in four hours the hemorrhage was completely checked. The cough was also markedly lessened. Three recurrences of the hemorrhage were promptly checked by the suprarenal substance. The patient made a fair recovery.

Case XIV.—Mr. J. G., aged forty-one years, married, had pulmonary tuberculosis. An attack of hemoptysis which resisted treatment for sixteen days was completely checked in six hours after beginning suprarenal treatment. No recurrences were noted.

Case XV.—Mr. G. C., aged twenty-nine years, married, had pulmonary tuberculosis. Overexertion caused an attack of hemoptysis which was promptly checked by the suprarenal powder. A slight recurrence was also promptly checked by the drug. A rapid recovery ensued.

Case XVI.—Mrs. M. M., aged twenty-four years, had pulmonary tuberculosis and mitral regurgitation. While in bed she was attacked with hemoptysis. The rapid administration of the suprarenal powder was followed by a prompt decrease in the hemorrhage, which persisted under suprarenal treatment for two days. Recovery was fairly rapid.

Case XVII.—Mrs. T. A., aged twenty-seven years, had pulmonary tuberculosis. Climbing brought on an attack of hemoptysis. The hemorrhage rapidly subsided under suprarenal treatment. Six doses were administered and no recurrence of the hemorrhage was observed for three weeks. A rapid recovery ensued.

Case XVIII.—Mr. J. R., aged thirty-one years, married, had pulmonary tuberculosis. Hemoptysis due to exertion was promptly controlled by the internal administration of the suprarenal substance. No recurrences were observed and a rapid recovery followed.

Case XIX.—Mr. J. F., aged fifty-one years, married, had pulmonary tuberculosis and acute cardiac dilatation. An attack of hemoptysis was controlled in less than ten minutes after the first dose of the suprarenal substance. A stimulating effect on the heart was observed. Recovery was rapid.

Case XX.—Mr. C. D., aged forty-five years, married, had an attack of hemoptysis due to pulmonary tuberculosis. The usual remedies failed to benefit at all for twenty hours. Suprarenal substance diminished the hemorrhage in twenty minutes. This persisted for two days, even when the suprarenal treatment was pushed. Recovery was fairly rapid. Three recurrences were observed after two weeks which were with difficulty controlled by the addition of other remedies and measures to the suprarenal treatment. Suprarenal treatment alone did not check the recurring hemorrhages.

Case XXI.—Mrs. H., aged thirty-six years, had an attack of hemoptysis. No cause was discoverable. After aconite, belladonna, hyoscyamus, nitroglycerin, digitalis, ergot, benzoin, etc., failed to benefit, suprarenal treatment was begun and all the other remedies stopped. In two hours the hemorrhage which had persisted for three days was completely checked. A rapid recovery followed.

Twenty-three Cases of Uterine Hemorrhage from Various Causes.

Case I.—Mrs. M. T., aged forty-nine years, had an attack of uterine hemorrhage due to carcinoma. Suprarenal treatment was administered and a prompt cessation of the hemorrhage occurred. A return of the hemorrhage, three weeks later, was also promptly checked by the suprarenal.

Case II.—Mrs. W., aged fifty-eight years, also had an attack of uterine hemorrhage due to carcinoma. The administration of the suprarenal powder was followed by a prompt checking of the hemorrhage. No return of the hemorrhage was noted for six weeks.

Case III.—Mrs. B., aged sixty-six years, had a similar history to Case II., only that the hemorrhage was not so promptly checked. Fifteen minutes at least elapsed before the hemorrhage began to diminish.

Case IV.—Mrs. K., aged twenty-eight years, had an attack of postpartum hemorrhage following a protracted labor. There was uterine inertia. The suprarenal powder in eight minutes diminished the hemorrhage considerably. The uterus soon thereafter was firmly contracted and the patient recovered rapidly.

Case V.—Mrs. G., aged twenty-one years, had a similar history to Case IV. The suprarenal powder also worked admirably.

Case VI.—Mrs. M. S., aged thirty-six years, also had a history similar to Case IV. The effect of the suprarenal powder was more rapid in this case.

Case VII.—Mrs. S., aged twenty-six years, had an attack of postpartum hemorrhage following an apparent normal labor. The uterus was soft and flabby. The suprarenal powder was administered and in ten minutes the hemorrhage was almost completely checked and the uterus was contracted. Recovery was rapid.

Case VIII.—Mrs. M. G., aged thirty-three years, had a similar history to Case VII. The same beneficial effects were also observed.

Case IX.—Mrs. C., aged twenty-nine years, had a similar history to Case VIII. The same beneficial effects were also observed in this case.

Case X.—Mrs. M. R., aged nineteen years, had an apparent normal childbirth. On the third day

she sat up in bed and at times would stand up. Uterine hemorrhage was brought on which was promptly diminished by the suprarenal. Removal of the clots from the uterus was necessary before the hemorrhage completely ceased. Recovery was rapid.

Case XI.—Mrs. M. K., aged thirty-six years, had a profuse uterine hemorrhage due to an incomplete abortion at six weeks. She was almost exsanguinated, unable to speak and she had six attacks of syncope within fifteen minutes. The pulse could not be felt at the wrist. In fact she was moribund. Suprarenal powder was administered and in six minutes the hemorrhage had almost ceased, the pulse became perceptible at the wrist and the uterus began to contract. Removal of all the secundines by operative procedure completely controlled the hemorrhage. Recovery was protracted.

Case XII.—Mrs. I. H., aged twenty-eight years, had an attack of uterine hemorrhage due to an incomplete abortion. Pressure on the fundus expelled the uterine contents, but failed to check the hemorrhage. The suprarenal extract markedly decreased the hemorrhage in ten minutes and checked it in four hours. Recovery was rapid.

Case XIII.—Mrs. C., aged twenty-seven years, had a similar history to Case XII. The same beneficial results were obtained with the suprarenal extract.

Case XIV.—Mrs. E., aged thirty-nine years, had a similar history to Case XIII. The same beneficial effects with the suprarenal extract were also noted.

Case XV.—Mrs. A. C., aged twenty-seven years, had symptoms of threatened abortion at four months. The suprarenal powder checked the hemorrhage almost immediately, the pains began to disappear and the uterus became softer. Suprarenal was administered four times a day. Recovery was rapid and abortion was averted. The patient was afterward delivered of an eighth-month infant.

Case XVI.—Mrs. M. O'C., aged thirty-two years, had a similar history to Case XV. The administration of the suprarenal powder was followed by admirable results. In both cases the abortion was averted and pregnancy went on uninterrupted to full term.

Case XVII.—Mrs. C., aged twenty-six years, had a similar history to Case XVI. The beneficial effects of the suprarenal powder also became rapidly apparent.

Case XVIII.—Mrs. H. G., aged twenty-two years, had an attack of threatened abortion at ten weeks. The hemorrhage, which was profuse, was considerably diminished in less than a half-hour after the administration of the suprarenal extract. The dose was repeated every half-hour. The uterus soon began to contract and expelled its contents with only a slight loss of blood. No recurrence of the hemorrhage was noted and the patient made a rapid recovery.

Case XIX.—Mrs. E., aged thirty-nine years, had a similar history to Case XII. The suprarenal also checked the hemorrhage quite rapidly. Though convalescence was slow the patient made a good recovery.

Case XX.—Mrs. I. S., aged thirty-seven years, had an attack of hemorrhage following a complete abortion. Pressure on the fundus and hot acetic acid douches gave but little relief. Suprarenal powder diminished the hemorrhage considerably within fifteen minutes and in three hours it had almost entirely ceased. The dose was repeated every two hours. Recovery was uninterrupted.

Case XXI.—Mrs. M. D., aged twenty-nine years, had a similar history to Case XX. The administration of the suprarenal powder was followed by its usual powerful and rapid results. Recovery was exceedingly rapid.

Case XXII.—Mrs. I. S., aged thirty-eight years, had a similar history to Case XXI. The administration of the suprarenal powder was followed by marked benefit. Recovery was rapid.

Case XXIII.—Mrs. M. O'G., aged twenty-three years, complained of uterine cramps and continued hemorrhage three weeks after labor. Curettage failed to stop the hemorrhage altogether. The administration of three doses of the suprarenal substance completely and permanently controlled the hemorrhage. The patient's recovery was rapid.

A Case of Hematemesis.

Mr. J. M., aged forty years, married, had an attack of appendicitis complicated by malaria of the tertian type. He was convalescing from his illness when he was attacked with a severe hematemesis which was probably due to the continued use of saline cathartics. The usual treatment did not benefit any in ten hours. The suprarenal substance was then employed and in fifteen minutes the hemorrhage was markedly decreased. The dose was repeated every half-hour. In three hours the hemorrhage was completely checked. No return of the hemorrhage occurred four weeks after. The patient recovered.

HYSTERICAL HEMIPLEGIA TREATED BY SUGGESTION, WITH REPORT OF A CASE.

BY HENRY LYLE WINTER, M.D.,

OF NEW YORK;

CLINICAL INSTRUCTOR IN DISEASES OF THE NERVOUS SYSTEM, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE (MEDICAL SCHOOL OF THE NEW YORK UNIVERSITY); ASSOCIATE IN ANTHROPOLOGY, PATHOLOGICAL INSTITUTE OF THE NEW YORK STATE HOSPITALS.

The following case is fairly typical of a by no means rare class of cases which should always be borne in mind in attempting differential diag-

noses of disorders of the central nervous system. For this reason and because, in this country at least, records of such cases are not common, I venture to report the present case *in extenso*.

Edward S., married, aged thirty-eight years. Born in United States of German parents. Occupation, barber.

Family history: Grandparents, negative. Mother died of apoplexy during confinement, aged thirty-eight years. This was the second attack. First attack three years previous. Mother's only brother living and well, but of very emotional nature. Father, living at present, aged seventy years, suffers from double cataract. Two of father's brothers became blind at about same age from the same cause.

Personal history was negative up to ten years of age. The death of his mother occurred at this time and was announced to him under conditions which excited him greatly. He became mentally depressed and at the funeral attempted to throw himself into his mother's grave. From that time he has continued to be very emotional, and at present laughs and cries without provocation, not infrequently laughing when the occasion calls for serious action. These emotional outbreaks are so pronounced as to interfere with his business and the discipline of his home. At eleven years of age, the patient had an attack of Bell's palsy, which has never entirely disappeared. He has had no other illness up to April, 1899. At that time he says that while asleep he dreamed that he was falling, and awoke to find a considerable loss of power in the right hand and, somewhat less marked, in the right leg. His voice, previously firm and clear, became weak and husky. He told his wife that he had had a "stroke." These symptoms continued for about two months, during which time he was under treatment. The arm recovered first and then the leg. Patient says that speech never became perfectly normal. Patient has always had the well-defined idea that he would die of paralysis, and the same idea was apparently held by other members of his family. He had been bowling considerably about the time the above symptoms appeared, and his family had told him to stop that form of exercise because it would lead to paralysis. He, himself, ascribed the condition to excessive bowling. On November 13, 1899, he began to suffer with severe occipital headache, which continued for several days. On the 17th, four days after the onset of the headache, the right hand began to feel numb and weak and the headache ceased. About two hours later the voice began to diminish in volume, and after the lapse of about two hours more the leg began to feel "lifeless."

I first saw the patient three days later, November 20, 1899. At that time there was a right hemiplegia with almost complete aphonia. The paralysis was more marked in the leg than in the arm. Pressure on the dynamometer registered 40 with the right hand and 100 with the left. The superficial and deep reflexes were slightly increased on the right side. The muscles were slightly spastic. Irregular spots of partial anesthesia were present on the dorsal surface of the hand, over the right deltoid muscle, and on the right side of the face. There was complete anesthesia about the mouth on both sides. Examination of the throat by Professor Coakley revealed a perfectly healthy larynx without any paralysis. The emotional condition above referred to was very marked; patient cried during entire examination. Heart, arteries, and kidneys were normal.

The history and condition of the patient were suggestive of a psychical origin for the hemiplegia and I decided to treat him on that basis. I gave the patient positive assurance of speedy recovery and advised him that the leg would recover first, then the arm, and, finally, the voice. I then prescribed ammoniated tincture of valerian in dram doses, repeated three times daily, and told patient that his leg would be much improved when he returned.

On November 27th patient reported improved. The paralysis in the leg was greatly diminished. Dynamometer registered a pressure of 50 with the right hand and 100 with the left. Condition of voice unchanged. Reflexes still slightly increased on right side. The anesthetic spots have disappeared from the hand and diminished in size over shoulder, but remained the same on the face. Patient was advised that the leg would be entirely free from paralysis when he next returned, and that the arm would be greatly improved and voice stronger. Medical treatment continued.

December 4th patient again reported. The paralysis had entirely disappeared from leg. Dynamometer registered a pressure of 65 with the right hand and 105 with the left. Reflexes normal. Condition of voice unchanged. Anesthetic areas had disappeared from shoulder and diminished in size and degree on face. The valerian was continued and patient advised that by the time of his next visit he would be entirely well.

Patient reported on December 11th. At this time the paralysis in arm had disappeared. Dynamometer registered 110 right and 100 left. Reflexes normal. The aphonia, however, was still present. The inability to speak above a whisper did not appear to the patient to be of grave consequence, and he ceased treatment.

While the aphonia and the anesthetic areas were suspicious elements and the case had recovered in the manner suggested and without medical treatment, I was unable at that time to decide positively that the origin of the condition was purely psychical. The possibility of its having been due to some temporary occlusion in the cerebral circulation, thus of organic origin, could not be overlooked. I made a note in my case-book merely to the effect that the case was *probably* of psychical origin, basing my opinion, as suggested above, on the patient's history as well as on the conditions.

On December 12, 1900, about one year after the occurrence of the conditions just mentioned,

the patient came into my office dragging the right leg and with the right arm hanging. He could not speak above a very low whisper and it was only by putting my ear close to his mouth that I could hear what he said. He pronounced the words properly, but seemingly with great effort. He said that, except for a weakness in his voice, he had been perfectly well from the time I had last seen him until two days before. At that time he went to his home, after bowling for about two hours, and was preparing for bed when he felt dizzy. He sat down and almost immediately lost consciousness. This lapse of consciousness lasted for about five (?) minutes and when he recovered he could not move his arm or leg nor make himself heard when he tried to speak. He suffered from a slight occipital headache and soon fell into a deep sleep which lasted all night. In the morning he felt well, with the exception of the paralysis.

On examination I found a complete right hemiplegia, including the face. (At the first attack there was no paralysis of the face except what remained of the old Bell's palsy.) The muscles were in a spastic condition and the leg and forearm were contracted. The reflexes were only slightly increased. The vocal cords and larynx were not examined. The entire right side of the face was anesthetic, but there were no areas of anesthesia elsewhere.

This time I concluded if possible to decide the nature of the paralysis and gained the patient's consent to induce hypnosis. I made him no promises beyond stating that I believed the treatment would be of benefit to him. During the first three days I was unable to induce anything but a light sleep, failing to get the patient to respond to any suggested movements. At the fourth trial, however, the sleep was considerably deeper. In this state the conditions remained unchanged. At this time I told him that I was going to apply a very powerful drug to his tongue, after which he could speak distinctly. Taking a swab of cotton I wet it with warm water and applied it to the tip of the tongue, at the same time asking, "How do you feel now?" "Very well, thank you," the patient replied in a moderately strong voice. I then told him that I was going to awaken him and that after five minutes he would feel that his tongue was warm and would speak about it, his voice being strong and natural. After awaking him I waited six minutes and then as he failed to speak, asked him if everything was all right. He shook his head, but said nothing and after waiting a moment took up his hat and said that he was going home. His voice was about the same as before the hypnosis.

The same plan was pursued on the following day. About five minutes after I had awakened him he suddenly put his hand up and touched his tongue at the same time saying, "Doctor, my tongue burns." His voice was loud and clear, but he evidently did not notice this fact because when I said "Why, your speech is all right now," he began to deny it, but was convinced by the continuation of its full volume, and became greatly excited. After the excitement had subsided I examined him and found that the paralysis of the face had also disappeared (except, of course, the remains of the old Bell's palsy.) The patient conversed with me for several minutes, the voice retaining its strength and fulness.

On the next day the voice still continued strong and has remained so to date (June, 1901.) The paralysis of the face had not returned. Patient was again hypnotized and asked if he could walk without dragging his feet. He replied that he could not. "Yes, you can," I replied. "Try it!" He refused to try and I again ordered him to walk. This time he stepped, but dragged his leg. The command was repeated. He hesitated for a moment and then walked normally. I asked him what the trouble with his arm was and he replied that it was paralyzed. I told him that it was not, and ordered him to put it out. He tried but apparently could not; then tried again with greater success. I urged him to put it out straight and he complied without hesitation. I placed the dynamometer in his hand and commanded him to press it, which he did, registering 100. After making him exercise the arm in various ways I told him that the paralysis was all gone, and that it would never trouble him after he woke up. Then seating him, I told him to open his eyes. For a few minutes he sat watching me while I wrote and then, apparently forgetful of the former paralysis, reached out his right hand and took his hat from the table. I then bade him good morning, and he left without making any reference to his condition.

The next morning he returned accompanied by his wife, who said that while he had used his arm and leg well, he had been stupid and dull since he arrived at home the preceding day, and had failed to take any interest in things which ordinarily appealed to him. Patient appeared still to be partially under hypnotic influence, and I accordingly re-hypnotized him and after repeating the same commands as on the previous day I told him that he would be wide awake as soon as I touched his eyes and told him to open them. After I had done this the patient remained seated for a moment and then jumped up and began walking up and down the room considerably excited. I spoke to him and he immediately controlled himself and sat down and talked rationally. There was absolutely no paralysis (except, again, the remains of the Bell's palsy), and the voice and speech were perfectly normal.

The patient reported to me from time to time up to May 1, 1901, when he left town. There has been no return of the trouble but the emotional disturbances still occur, though not so frequently.

In using the term "hysterical" in this case I am following a time-honored custom with which I am not in sympathy. "Hysterical" in this sense means either that the paralysis is an incident of an attack of hysteria or else that it has

no known anatomic basis. In the latter case "hysterical" and "functional" are synonyms and are meaningless labels which we put upon certain diseases while waiting for some one to demonstrate the underlying physical bases.

It is not impossible that in the field of nervous diseases our hopes in this direction may ultimately be realized, though a review of the progress and status of neuropathology is not particularly encouraging. At any rate, even if some of these obscure conditions do not lie beyond reach of microscopic examinations of dead tissues, it must take years of patient research before the tissue changes, if any exist, are revealed. In the meantime we may elect to wait for the pathologist or we may attempt a purely theoretical explanation of the conditions. The latter is, in my opinion, the more scientific plan.

Several theories have been advanced, the most widely known of which is probably that of the Nancy School.[1] The conceptions of Bernheim do not, however, appear to explain the various conditions with which we come in contact clinically. My own views are based upon the theories advanced by Sidis,[2] which leave as little to be desired by the medical mind as any purely theoretical explanation.

As a first step in what we may call our psychophysiological theory, we must accept the further theories of the neurons and of neuron retraction. Attempts to prove by histological research that the contact between the neurons is a physiological process and not an anatomical state, and that neurons retract, have proved of negative value; but Van Gieson[3] has shown, reasoning by analogy, that neuron retraction should exist. The results of the researches of Apathy and others, which indicate the existence of a true anatomical connection between the neurons, were gained by examination of the lower, automatic centers where we would expect to find such conditions, and are of no value whatever as arguments against the retraction theory.

According to the psychophysiological theory, cerebral activity, accompanied by consciousness which is expressed in sensory, volitional, and intellectual processes, is the result of the activity of certain cells which are grouped, or aggregated, or associated into a psychical center (producing a psychical process) by means of the movements of their terminal end-brushes in response to certain stimuli. The normal condition of any neuron (or group of neurons) entering into any psychical process, consists in the contiguity of the terminal end-brush with the dendrons of its neighbor (or associate.) If we accept this theory as explaining normal psychical activity or normal consciousness, it is evident that abnormal consciousness or psychical disturbance would result from any failure of the terminal end-brush of any neuron to establish the proper contact with its neighbor. If the neuron were retracted the center would cease to exist, its components being disaggregated or dissociated. Postulating that retraction does exist, its causes may be a traumatism, infection, autoinfection, cardiac or arterial disease, mental shock, prolonged mental concentration (autosuggestion), or suggestion. The clinical evidences of retraction, or, perhaps I had better say, the clinical phenomena explainable by the theory of retraction, are numerous; disturbances of motion like the case above reported, many forms of insanity, abnormal mental states which do not fall within any of our classes of insane, paroxysmal attacks of pain of a neuralgic type, many of the phenomena of neurasthenia and hysteria, and, perhaps, certain joint, visceral and vesical affections. Therapeutically, the theory is that properly-applied suggestion, no matter what its origin, acts to overcome this neuron retraction and restores the association between the neurons, thus re-establishing the group of aggregation. It is evident that in the mental condition which we recognize under the name of the *subconscious state* there must be less resistance to suggestion than when the subject is actively conscious, and for this reason suggestion under hypnosis is more often successful than it is without it.

In the case herein cited we must consider two sets of neurons which we know anatomically as motor cells and their processes, and also certain other sensory-motor (psycho-motor) neurons which have not been isolated, but which we suppose form the higher or volitional portion of the motor apparatus. The neurons which we know as anatomical entities are an upper set extending from the motor (sensori-motor) region of the cerebral cortex to the anterior horn of the spinal cord, and a lower set extending from the anterior horn to the periphery. The neurons which we have by any histologic research been unable to associate with the motor apparatus (but which none the less must be a part of it) are the cells and fibers lying principally within the parietal cortex, designated by Starr as the sensori-motor cortex. Under normal conditions these several sets of neurons are physiologically associated and motor impulses arising in the cells of the sensori-motor cortical areas are transmitted through their processes to the cerebral motor neurons and thence by the spinal motor neurons to the periphery, finding expression in muscular movement. In an organic cerebral lesion involving the cortex it is probable that the higher sensori-motor neurons are destroyed (or impaired) as well as the cerebral motor neuron. If, however, the lesion occurs in the internal capsule or in the pyramidal tract, it includes only the motor neuron, the impulse does not reach the lower neuron at all, and a paralysis results. In the latter instance the impulse originated properly and it failed of its normal result of muscular motion merely because of the destruction of the integrity of its pathway of transmission.

Logically, there is no reason why we could not have a physiological as well as an anatomical

[1] Bernheim. Suggestion Therapeutics.
[2] Sidis. "The Psychology of Suggestion."
[3] Van Gieson. Address before the American Medico-psychological Association, 1899.

solution of continuity in this pathway. Therefore in the case herein cited my theory is that the paralysis was brought about, not by disease of the nerve process, but by a retraction of the terminal end-brushes of the sensori-motor (psycho-motor) neurons, thus preventing the impulse from reaching the distinctly motor neurons. The etiologic factors were an inherited predisposition or mental instability, shock at the age of nine years (increasing the instability), and the fear of paralysis kept constantly in the foreground of the patient's consciousness by his family (suggestion) and himself (auto-suggestion). Suggestion may thus be regarded as the exciting cause. This being the case, the desired therapeutic results would be gained by anything which would remove the effects of this suggestion. Logically, counter-suggestion (if the term may be allowed) should act in the desired manner and, clinically, it *did* so act.

As may be inferred from what I have written, it is my desire in reporting this case not merely to make a contribution to medical literature, but to endeavor to impress the medical profession with the necessity of taking a scientific view of this class of cases. If the profession as a whole would take cognizance of and endeavor to deal intelligently with the element of suggestibility which is so prominent in the mental make-up of the human species, the greatest benefit would result.

It is true that cases like the one I have cited have been treated and cured by suggestion employed on purely empirical grounds, but there are cases, more especially of a mental type, in which this will not hold true. In any event empiricism is the stronghold of the charlatan and suggestive therapeutics have fallen under the ban of suspicion because of it. The result is that the medical profession either ignores so-called "functional" and "hysterical" diseases, or puts them to one side as of little consequence or beyond comprehension. If, instead of this attitude, we will adopt some theory which explains these conditions, we will have placed them in a position to be intelligently and scientifically dealt with. I have, therefore, ventured to advocate the theory herein outlined which (of course, theoretically) not only locates the disease, but describes the nature of the "lesion." The acceptance of this theory brings us to the necessity of dropping the terms "functional" (though the diseases are functional in so far as they are not organic) and "hysterical," and substituting a word indicative of a disturbance of psychical activity or consciousness. Apparently "psychical" is the best term, and it also has the advantage of having been in use for some time.

Sufferers from these "psychical" diseases are the ones who are cured by Christian Science, who throw away their crutches after viewing a "sacred relic," or visiting the shrine of a "departed saint," who became well after visiting the osteopath, and upon whom the numerous other charlatans work beneficial results. There is no question but that the wily devotees of these various "opathies" effect cures, and were they able to realize their own limitations, perhaps the only objection which could be urged against their existence would be the fact that they absorb too large a proportion of their client's worldly goods. But through their ignorance they fail to distinguish between the "organic" and the "psychical" in disease, and the sums of their errors and their iniquities are increasing daily. If the medical profession will take cognizance of what we may call the "immaterial" side of human ills and will proceed in a scientific manner it may cure in a legitimate way what the charlatans cure by their false doctrines, and may avoid their mistakes. It is not unusual to hear otherwise intelligent men say that "there is something in Christian Science," failing to realize that the element of good which is supposed to be in it and in all other fictions is in reality within the patient himself: *it is the very important and wofully-neglected element of suggestibility.*

We have recently had a demonstration of the futility of attempting legislation against the "opathies;" but their existence would be short indeed if the medical profession would interest itself as earnestly in the "psychical" diseases as it does in the "organic." Once let the medical profession do for a legitimate fee what Christian Science now does for the half (or whole) of one's fortune and the public will not be slow to leave the impostors to take care of themselves.

147 Hancock Street.

THE REQUIREMENTS OF MODERN SURGERY.[1]

BY J. H. CARSTENS, M.D.,
OF DETROIT, MICH.

If you ask what is modern surgery, I would answer that it is the gospel of cleanliness—*that covers the ground.* Here the problem presents itself and also the difficulties, and here are our failures manifested because of the utter impossibility of absolutely preventing infection in every case.

(1) The great point in connection with successful surgery is the individual to be operated upon. We have minimized the chances of infection of the individual himself, so that, as far as the patient is concerned, we are able to get the site of operation reasonably clean.

(2) The patient is clean, but you cannot operate on his unclothed body. The patient must be covered—kept warm in fact. We insist on absolute sterilization of everything touching the patient, of everything that is in the operating-room; this includes tables, chairs, basins and bowls, and everything that may be used. Considering all these points about the requirements of modern surgery, I believe it to be utterly impossible to carry out modern aseptic surgery in a private house.

Every surgeon understands that I want to call

[1] Abstract of a paper read before the Michigan State Medical Society, 1901.

attention to the fact that the highest and most perfect type of surgery, the technic, the rapidity of the operation, with lessened danger from shock, and the most careful judicious after-treatment of the patient can be better carried out in a well-equipped hospital than in a private house.

(3) Another great requirement of modern surgery is in the surgeon himself. The question of individuality always comes to the front and the power of adaptation to environment of an individual is far greater than the power of environment to shape the course of a person. A patient in perfect health with the greatest power of resistance, the most beautifully equipped hospital, or the most perfectly-arranged operating-rooms, the well-trained nurses, the alert assistants, cannot compensate for a *poor operator.*

When anesthesia was used and the patient was free from pain, slower and more careful operating was allowable, and, in the course of time, this tendency to slowness and deliberation has crept more and more into the ranks of surgery.

Should anyone hint to those of insufficient training that they are not competent to practise surgery because of lack of training, they would feel very indignant, and would probably say, "Why, you had to learn. You killed a lot of patients learning this." That may be, *because we were obliged to in order to open the path for the future, in order to save life and lessen the suffering for coming generations.* That does not say that every Tom, Dick and Harry has to learn this over again, and should make the same mistakes we made. We made the mistakes and in the light of knowledge so acquired we have tried constantly to teach the rising generation of surgeons how to *avoid the mistakes.*

No one can become a modern surgeon by going to a post-graduate school and seeing a surgeon operate at a distance of fifty or a hundred feet. In order to become a modern surgeon he must work directly with some modern surgeon, *he must assist him, he must be with him day after day, month after month—yes, even year after year, but certainly not less than a year.* Then he will probably appreciate the difficulties of diagnosis, the difficulty of deciding upon the right kind of operation, the difficulty of selecting the propitious time and moment for each individual patient. Then he will acquire some of the fine points in the technic, the minutiæ, the attention or non-attention to which small details brings success or failure in an operation.

The man who has never done any mechanical work, who was not allowed to make a little sleigh or a baseball bat when he was a boy, or who never worked in the garden, or played ball, or the piano, or who never made pills in a drug-store, the man who had never developed a mechanical hand from his earliest childhood, will never be a good surgeon. The man who simply studied all his lifetime and whose father was kind enough to buy him everything from a wagon to a book, who was never taught to draw and to cultivate an artistic eye or develop the sense of symmetry and proportion, that man will never be a surgeon; such is not in the nature of things.

Finally you will ask me, "Who could or should be a surgeon?" and in answer I will say that he must be a well-educated physician, must have been a general practitioner and a good therapeutist. He must take up surgery early and gradually develop a surgical hand; he must have been assistant to a first-class surgeon for at least a year, where he will see hundreds of operations of various kinds. Such a man may be a good surgeon. He ought to be in some large town, say a county seat, and, as his surgical practice grows, he should give up absolutely general practice, devoting himself to surgery exclusively, and then his colleagues in the county would support him.

Hence the requirements of modern surgery are: (1) A patient brought to the highest state of resistance to microbic infection and made as clean as possible; (2) an operating-room, preferably in a hospital where everything has been made thoroughly sterile; this includes anesthetizers, assistants and nurses; (3) a surgeon who has a mechanical hand and has received a long and thorough training.

ON THE ABSORPTION OF ALEXINS BY TUBERCLE BACILLI.[1]

(Preliminary communication.)

BY P. A. LEVENE, M.D.,
OF NEW YORK.

IT HAS been shown by different investigators that bacteriolytic or hemolytic sera when digested with dead bacteria of different species lose their bacteriolytic power over other bacteria and also their hemolytic power. If, instead of dead germs, bacteria previously treated with a bactericidal serum heated at 55° C. be allowed to act on a bacteriolytic or hemolytic serum, the latter will lose its power to dissolve other bacteria or red cells. On the other hand, living bacteria fail to produce any effect on a normal serum which has no bactericidal power over the same bacteria.

Speaking in terms accepted by the workers in this line of research, one would have to say that dead bacteria of different species possess the power of absorbing alexins from normal sera. Living bacteria do the same only after they have been previously saturated with the "immune body." They will also absorb the alexins from a serum which has been obtained from an animal immunized against the same germ. Or, in other words, if a given serum loses its alexin on treatment with a living germ, it is safe to say that the serum possesses a bactericidal power over the same germ. Thus, the presence or absence of alexins in a serum treated with living bacteria could serve as an indicator for the presence or absence in it of bactericidal power over the same bacteria. Bordet first recurred to this method in order to prove the presence of "im-

[1] From the Saranac Laboratory for the Study of Tuberculosis, Dr. E. L. Trudeau, Director.

mune bodies" in bactericidal sera. To my mind this is the only method to which one can recur at present for the study of bactericidal power of a serum against a germ that grows like the tubercle bacillus. As is well known, the method of "plate counting" cannot be applied to the tubercle bacillus for this purpose.

In order to apply this method for the study of artificial immunity in tuberculosis the following questions had to be investigated: (1) Whether normal sera lose their hemolytic power on digestion with dead tubercle bacilli; (2) what the hemolytic power of a given serum would be if treated with living bacilli; (3) if an animal should be found whose serum normally does not lose its hemolytic power on treatment with living bacilli, would the serum of a tuberculous animal act differently?

My experiments thus far have been limited to the reaction of the rabbit serum to tubercle bacilli. Two different growths of bacteria were used. One had been constantly transplanted for many years on beef-broth media, and would fail to produce acute tuberculosis in the rabbit (these cultures will be referred to as attenuated); the other was a culture which had been very virulent for dogs about six months ago, and since then had been kept up on serum-tubes. Four-day-old tubes were used (they will be referred to as "virulent" cultures).

As a result of my experiments I wish to mention, first, that there exists a certain "minimum" quantity of dead tubercle bacilli, which it is necessary to add to a given serum in order to deprive it of its hemolytic power. On addition of smaller quantities of the germs the hemolytic power is only diminished, not wholly abolished; second, living virulent bacilli added in quantities approximately equal to the "minimum" of the dead bacilli have scarcely any effect on the hemolytic power of a serum; added in larger quantities they diminish the hemolytic power of a serum, but in a lesser degree than do dead bacteria.

Further, I found that the "attenuated" cultures act in the same manner as the dead germs.

When the serum of an animal previously treated with the extract of crushed tubercle bacilli is tested with living virulent bacteria it loses its hemolytic power much more readily than does a normal serum.

Dr. Baldwin and myself are engaged in the further investigation of all these questions. We are also engaged in experiments in the same direction with the bacillus of cattle tuberculosis with a view to approaching the question of the transmission of cattle tuberculosis to man and *vice versa*.

One More Cure for Consumption.—A Cracow correspondent says that M. Ryshnowski, a Polish engineer, has discovered a new gas called electroid, which doctors there and at Lomberg are prescribing for consumption. It is inhaled for periods ranging from half a minute to a quarter of an hour. It is also said to be effectual in anemia and neuroses.

MEDICAL PROGRESS.

THERAPEUTICS.

Improved Method for Introduction of Stomach Tube.—The serious objection of nausea and gagging upon the introduction of the stomach tube, especially for the first time, has caused its abandonment in many cases where its use is fully indicated. H. Crenshaw (Med. Rec., Dec. 21, 1901) has devised a novel method which, he says, obviates this disagreeable feature. The end of tube is frozen for two or three inches by ethyl chloride and when introduced causes anesthesia of the mucous membrane to which it is applied. It may thus be introduced, for the first time, with practically no gagging, straining, or nausea. When it reaches the stomach the temperature has been sufficiently raised to cause no harm to the gastric mucosa.

Urea in the Treatment of Tuberculosis.—The value of nitrogenous products in the treatment of tuberculosis is regarded by H. Harper (The Lancet, Dec. 7, 1901) as in scientific harmony with the belief of Sir Dyce Duckworth and others, in the apparent immunity of gouty persons to tuberculosis. At the British Congress on Tuberculosis Sir H. Weber stated that out of 25 cured patients within his knowledge 18 had developed gout in some form. In some way urea is believed by Harper to increase the natural immunity of the individual to tuberculosis. Whether it stimulates the phagocytes or increases the bactericidal property of the serum or stimulates the cells to elaborate antitoxin remains to be proved. A number of tuberculous cases, some of long standing, some of recent invasion, are described by Harper, in which a synthetic urea was successfully used. Cases suitable for this treatment are classified as follows: (1) Circumscribed pulmonary tuberculosis in which the sputum exhibits an abundance of tubercle bacilli and only a few cocci; (2) enlarged tuberculous glands; (3) tuberculous pleurisy; (4) tuberculous laryngitis; (5) lupus; (6) tuberculosis of the peritoneum with free fluid; (7) tabes mesenterica. Cases of acute miliary tuberculosis with high temperature do not react favorably, nor were good results obtained in pulmonary tuberculosis when the temperature exceeded 101° F., or when the sputum showed a predominance of cocci. In carrying out the treatment doses of 10 or 15 grains were first given thrice a day, with gradual increase to 40 or 50 grains.

Therapeutics of Light.—In 1894 it was shown by Marshall Ward that the bactericidal action of light depends mainly on the violet and ultra-violet rays. Five years later Finsen called attention to these same rays as the cause of the effects of light on the normal skin. Since then, says S. Bang (Berl. klin. Woch., Dec. 9, 1901), practically no progress has been made in the study of the photo-biological principles upon which the modern light-therapy depends for its advancement. It is known, however, that the inflammatory phenomena resulting from the action of chemical rays on the skin differ from those produced by all other forms of irritation. There is a "positive" and a "negative" light-therapy. The latter rests upon the knowledge that chemical rays exert a harmful influence in certain cutaneous affections, and endeavors to withhold these injurious rays. This method has been used successfully in the treatment of local affections of the skin, and Finsen and others have applied it to the treatment of variola with apparently good results. The attempt to utilize "Finsen's red room" in the treatment of scarlet fever and measles has thus far given no convincing results. The "positive" light-therapy employs light for general as well as local treatment. For gen-

eral treatment sunlight and electric light are employed. The sun-bath is a very old method for the treatment of constitutional diseases. Rikli and Lahmann have revived it, but do not rely on it alone; they combine with the sun-bath fresh air and the process of "hardening," while Rikli in addition makes use of vegetarian diet. The knowledge that certain conditions can be improved by such combined treatment is clinically important but not scientifically interesting, because it is impossible to estimate the relative values of the various elements. The wonderful workings of the electric light in the treatment of general diseases are regarded by Bang as far from proved. It is too early to undertake the treatment of tuberculosis, syphilis, arthritis, diabetes and nephritis by this agency. The only branch of "positive" light-therapy which rests upon proper scientific and practical foundations is that which concerns itself with local treatment. Bang believes that the treatment of lupus by Finsen's method is destined to replace surgery and cautery. Over six hundred cases have been treated in Copenhagen, with positive results in 98 per cent. of the total number. The treatment of lupus erythematosus was less satisfactory. Alopecia areata can usually be cured in a few sittings; here, as in the treatment of acne vulgaris, the bactericidal action of the light rays asserts itself, while in nævus vascularis the irritation of the skin is the essential factor.

Galvanism in Sterility.—As it is generally believed that whenever lifeless spermatozoa are found in the semen soon after ejaculation has taken place, the patient is irreparably sterile, the following case reported by G. M. BLECH (Phila. Med. Jour., Dec. 7, 1901) should be of interest. His patient was a man of thirty-two, in fair general health, of good habits, with no history of syphilis, but an indefinite one of gonorrhea many years before. Married eleven years, no offspring. A specimen of semen was secured immediately after intercourse and examined. Spermatozoa were found, well developed, but lifeless. Tonics and hydropathic measures were used for three months, and then an examination disclosed no change. The electric current was then resorted to, the treatment consisting of negative galvanic applications to the prostatic urethra, five to twelve milliamperes. Twelve treatments were given (two per weeks), each sitting lasting from five to eight minutes. An examination after this showed numerous living spermatozoa. Pregnancy has since then been determined in the wife.

Artificial Light in the Treatment of Tuberculosis.—During the past few years considerable attention has been devoted in some quarters to the treatment of pulmonary tuberculosis and various other tuberculous lesions by the means of intense artificial light. A serious drawback to this treatment has been the expense of the apparatus necessary for its fulfilment and the great difficulty in regulating the dosage necessary for individual cases. F. DE COURNIELLES (Comptes Soc. Biol., Nov. 22, 1901) employs the voltaic arc for this purpose. The source of light is placed very near the patient, the heat rays being removed by a special apparatus designed for this purpose. In this manner one obtains with a voltaic arc of 5 to 12 amperes effects equal to those obtained by the employment of 80 amperes in other apparatus. A convex mirror concentrates the rays upon the desired region. This method gives a minimum amount of light and a maximum effect therefrom. Many cases of various tuberculous lesions have been successfully treated by this method, and its employment in all tuberculous conditions as a routine procedure is strongly urged.

Sensitiveness to Remedies.—From experiments on a number of animals of the same species and then of different species, E. MAUREL (Bull. géné. de Thérapeutique, Nov. 15, 1901) schedules the tissues in their order of sensitiveness to various therapeutic measures. The first tissue on the list is the most sensitive, the last the most resistant. For *heat* the order is leucocyte, striated muscle, cardiac muscle, sensory nerve, motor nerve, smooth muscle, blood. *Cold* gave the same results. *Emetine* affects in order smooth muscle, sensory nerve, striated muscle, cardiac muscle and the red and white blood-corpuscles. From the point of view of toxicity, that is, the order in which the tissues die, under *emetine* the list runs as follows: Sensory nerve, motor nerve, striated muscle, cardiac muscle, smooth muscle, leucocyte, and blood. *Bonjean's ergotine* gave the same order for toxicity and sensitiveness, viz., smooth muscle, blood, motor nerve, striated muscle, sensory nerve, leucocyte and cardiac muscle, the last two being practically the same, and the three preceding so close as to be difficult to determine. *Lead acetate* is the same for toxicity and sensitiveness; blood, smooth muscle, sensory nerve, motor nerve, striated muscle, cardiac muscle and leucocyte. *Strophanthin* affects cardiac fiber, sensory nerve, motor nerve, striated muscle, smooth muscle, blood and leucocyte, the same for toxicity and sensitiveness. For toxicity *mercury* gives leucocyte, blood, cardiac muscle, smooth muscle, sensory nerve, motor nerve, striated muscle; but for sensitiveness, smooth muscle comes last. For toxicity of *digitalin* the order is cardiac muscle, sensory nerve, motor nerve, striated muscle, smooth muscle and the blood-corpuscles. For sensitiveness, smooth muscle, cardiac muscle, sensory nerve, motor nerve, striated muscle, and the blood corpuscles. *Caffeine* gives for toxicity sensory nerve, motor nerve, striated muscle, leucocyte, blood, smooth muscle and cardiac muscle. For sensitiveness, the order is sensory nerve, motor nerve, striated muscle, leucocyte, smooth muscle, blood. *Sparteine* for toxicity, sensory nerve, motor nerve, striated muscle, cardiac muscle, smooth muscle, leucocyte, blood; for sensitiveness, smooth muscle, cardiac muscle, striated muscle, motor nerve, sensory nerve, leucocyte and blood. The application of these facts may be shown in the case of digitalin. It acts successively on smooth muscle, cardiac muscle, sensitive nerve; therefore, in order that digitalin may affect the sensitive nerve, it must first influence the smooth and cardiac muscles. Likewise its toxic effect is felt by cardiac muscle, sensory nerve, motor nerve, etc., that is, the cardiac muscle is the first to be poisoned.

Quinine by Hypodermoclysis.—In order to avoid the pain, induration and possible necrosis incident to the subcutaneous administration of strongly acid solutions of quinine in cases of pernicious or very severe estivo-autumnal malaria, when administration by mouth is impracticable, J. W. GRAY (Memphis Med. Monthly, Dec., 1901) uses one-fourth to one-half per cent. of quinine in normal salt solution by hypodermoclysis. By this method the eliminative action of the salt solution is added to the specific effect of the quinine; absorption is rapid and cinchonism prompt. In very urgent cases a similar solution may be thrown directly into a vein.

Treatment of Alcoholic Delirium.—Several suggestions, contrary to the generally accepted ideas in regard to the treatment of alcoholic cases, are given by T. D. CROTHERS (Med. Rec., Dec. 14, 1901). The removal of alcohol is the first step and this should always be done abruptly, even though the delirium continues or increases. Slowly withdrawing the alcohol, giving narcotics and overfeeding, is extremely dangerous treatment in some cases. Recovery is delayed and complications encouraged. Removal of the toxins must be accomplished as soon as possible. After the spirits

have been removed small doses of calomel and salines must be given till free catharsis results. A combination of magnesium sulphate and potassium bitartrate, two parts of the latter and one of the former, acts very well. Next in importance are hot-air and hot-water baths which should be given daily so long as the delirium continues and less actively throughout convalescence. Narcotics should be used sparingly for the vital centers are already depressed and the addition of chemical stupor is hazardous. For the craving for alcohol that follows the withdrawal, give strong solutions of quassia or cinchona, given every hour; these will soon break up this impulse and produce an intense disgust for spirits. Feeding is another important factor and since assimilation and digestion are enfeebled forced feeding is contra-indicated. The author's experience has been that small quantities of easily digested solid foods may be cautiously given after delirium has ceased, but that total abstinence during the early stage of delirium is productive of the best results. Liquid foods, he believes, are actually culture mediums for the formation of new toxins and perpetuation of the old ones. Restraint depends largely on the patient and in certain cases as much liberty as possible should be allowed. Cardiac failure seldom occurs, but strychnine and hot and cold water-bags over the precordium are safe and efficient remedies. For the insomnia and various neuralgias which follow the subsidence of the delirium baths, moderate exercise in the open air and static electricity are valuable measures. During the stage of delirium, which is usually self-limited, it is best to keep the patient in bed as much as possible, but if he insists on being up, he should be kept in a state of sharp muscular activity by means of baths, massage, or walking. When delirium subsides the muscle and nerve rest should be increased.

Treatment of Round Worms.—Undoubtedly santonin is the best drug used in cases of round worm, but it must be properly administered. J. P. Maxwell (Indian Med. Rec., Nov. 20, 1901), who has had a large experience in China where such cases are common, says that there are two classes of patients—those with urgent symptoms and the chronic cases. The former are best treated with a dose of oleum ricini, ℥i, and santonin, gr. iv. After a week has elapsed the treatment for chronic cases should be given. The latter do best on the following. Santonin, gr. i; hydrarg., c. cret., gr. i., given t.i.d. for several days. No ill effects were seen when this dosage was continued for several weeks. Another combination which works well is the above prescription with the addition of quinine sulph., gr. iij. The patient should always be warned about the disagreeable symptoms which may arise—xanthopsia, vomiting and sometimes a rise of temperature.

A New Valerian Preparation.—Valerian and its derivatives have fallen largely into disuse on account of their unstable character, disagreeablee odor, and in many cases, doubtful physiological effect. A new preparation is announced by Kionka and Liebrecht (Deut. med. Woch., Dec. 5, 1901) which is stated to obviate these difficulties. The new drug is marketed under the name of "Valyl" and is a diaethylamid of valerianic acid. It is a colorless liquid, of pungent odor and burning taste. It was tried in one hundred cases, without unpleasant after-effects and with the following results: (1) In hysteria, even of severe grade, with cardiac complications, the results were fairly good, also in several cases of neurasthenia and hypochondriasis. (2) Traumatic neurosis, hemicrania and various neuralgias were greatly benefited. (3) Menstrual pains, with the accompanying headache, were improved greatly, also the climacteric disturbances. The drug is given in capsules, each containing two grains mixed with a small quantity of tallow; from one to six may be taken, three times daily.

Gymnastics in the Bath.—Treatment by this system was first proposed by Leyden and Goldschneider in Germany and by Bozzola in Italy. Good results of personal experience in its application to muscular atrophy and partial paralysis of nervous origin are reported by G. B. Allaria (Riv. Crit. d. Clin. Med., Nov. 30, 1901). The fundamental principle of this method is derived from the physical law of Archimedes, *i. e.*, a body immersed in water loses weight in proportion to the amount of liquid it displaces. Its advantage lies in the lightening by immersion of the part to be exercised; thus enabling the patient to execute movements which would be impossible out of the bath. Many of the consequences of paralysis from cerebral hemorrhage, etc., are exaggerated by inertia of the patient; this method serves to combat the manifestations and consequences of affections of the nervous system by increasing the muscular nutrition and lessening the rigidity of joints. It is especially useful in tabetic paraplegia; this condition necessitating, however, long-continued treatment and the exercise of caution in its application owing to the fact that the tabetic sense of fatigue is blunted; and there is a consequent risk of continuing exercise beyond the physiological limit, thus increasing the degenerative processes of the nervous system by overfatigue. In such cases prolonged rest between treatments should be advised. In the class of cases in which motion is limited by pain, as in sciatica and rheumatism, exercise in the bath has been found valuable, both through the greater facility of motion and through the calming effect of warm water; and though the first attempts at exercise may be painful, the continuation of methodical movements seems to exert an inhibitory influence upon the pain. The simplicity and effectiveness of this treatment merits its wider knowledge and use, either alone or in conjunction with massage, passive motion, or electrotherapy. A daily bath should be given of 10 to 20 minutes' duration; the temperature being regulated according to the nature of the malady, and ranging from tepid (26°-29° C.) to hot (35°-39°) in painful affections. The efficacy of the bath may be increased by raising the specific gravity of the water by addition of sodium chloride or other salts. Like all other therapeutic measures, it has its contra-indications; notably in cases where there is a tendency to cerebral congestion, there is danger of provoking fresh hemorrhage, and in such cases it is well to keep an ice-bag upon the head.

Treatment of Dysentery with Peroxide.—This method of treatment was used with great benefit in ten cases ranging from two to twelve years of age by Rocaz (Jour. de Méd. de Bordeaux, Dec. 1, 1901). Lavage with hydrogen peroxide was practised 2 or 3 times daily; the effect was speedy and marked. Within two or three days the character of the stools changed materially; blood and mucus disappeared, the stools became less and less frequent, and the sphincter regained its tonicity. That a cure may be assured, it is necessary to continue medication some days after subsidence of symptoms.

Treatment of Hemorrhoids.—After a few days' application of the following remedies pain and hemorrhage disappear and at the end of from three to five months the hemorrhoids are completely retracted. Prior to application the parts should be thoroughly disinfected with carbolic solution. Ointment for external hemorrhoids:

℞	Chrysarobin	0.8
	Iodoform	0.3
	Ext. belladonna	0.6
	Vaseline	20.0

Suppositories for internal hemorrhoids:

R	Chrysarobin	0.08
	Iodoform	0.08
	Ext. belladonna	0.01
	Cocoa butter	2.00

—Jour. de Méd. de Paris, Dec. 1, 1901.

Rectal Injection of Ergotin for Metrorrhagia.—Where ergotin is not well borne by mouth, it can, after preliminary lavage, be injected by rectum, a teaspoonful of the following solution being used, in three tablespoonfuls of tepid water:

R	Ergotine	10.00
	Distilled water	70.00
	Glycerine	20.00
	Salicylic acid	0.20

—Jour. de Méd. de Paris, Dec. 1, 1901.

Creosote in Pneumonia.—Concerning the use of creosote in pneumona, J. L. VAN ZANDT (The Southern Pract., Dec., 1901) says that a large percentage are cut short or aborted, almost all the rest are mitigated, and only very few are not benefited by it. It is important that the medicine be not omitted as soon as the active symptoms subside, as there may be a recurrence. The carbonate is the best form; guaiacol and its salts do not seem to exert the same specific action.

SURGERY.

Abdominal Injury.—The non-operative treatment of severe abdominal contusions is a method which is regarded as inadvisable by E. LEXER (Berl. klin. Woch., Dec. 9, 1901). Statistics of severe contusion of the great abdominal organs, collected by Petey and others, show a mortality of over 80 per cent. where expectant treatment is followed. When injury of the stomach or intestine has occurred conservative (non-operative) treatment of the case must not be considered without a thorough review of the possible results of the injury. If adhesions form about the site of a perforation, these may at any time be torn. A crushed area of intestinal wall may become necrotic, with general peritonitis as the result. Abscesses may develop in the vicinity of the rupture or contusion, producing severe pains and fever; rupture of the abscess wall is always imminent, hence the possibility of general peritonitis suddenly developing. If such abscesses be opened and drained fecal fistulæ may form, requiring further operation. Cicatricial stricture at the site of the injury may cause serious chronic trouble. A large hematoma, intraperitoneal or mesenteric, may give rise to various pressure symptoms. Lexer illustrates by a series of clinical histories the many untoward results of abdominal contusions, and urges the necessity of operating at once on the appearance of the first suspicious signs of internal injury. Even where rupture of the liver has occurred the possibility of successful interference should encourage prompt interference. Wilms recently reported a case which was saved by prompt treatment. The two cases described by Lexer, however, terminated fatally.

Knife-wound of the Heart; Sutured; Recovery.—A soldier who had been stabbed came under the observation of M. FONTAIN (La Presse Méd., Dec. 4, 1901) nearly two hours after the receipt of the injury. He complained chiefly of precordial pain; respiration was not embarrassed; the pulse was 120, small, easily compressed, but regular; the heart-sounds were muffled and distant. The wound was in the third intercostal space and apparently extended downward and inward. Operation was at once begun, under chloroform. A flap was cut consisting of the anterior portion of the third, fourth and fifth ribs and intercostal tissues; this was turned outward. The left lung was found intact; the costophrenic sinus was filled with blood which issued from a pericardial wound about 12 mm. long. This wound was enlarged to permit the exploration of the heart, the apex of which was first seized with Kocher forceps. A wound about 8 mm. long was readily discovered over the left ventricle, perpendicular to the direction of the muscle-fibers of the heart, gaping, and giving vent to a jet of blood with each systole. The wound was sutured with catgut; the pericardial sac was cleaned and the pericardium closed by catgut sutures. The thoracic flap was turned back and its borders sutured. The operation consumed forty-five minutes in all. During the operation the needle with which the ventricle was sutured accidentally penetrated the wall of the heart and entered the cavity; to this accident was attributed a pulmonary infarction which occurred six days after the operation. Later the patient suffered from a pneumonia of the left base, complicated by an empyema which necessitated thoracotomy. Despite these accidents recovery followed. The present functional condition of the heart is not wholly satisfactory, tachycardia is present and the arterial tension remains very low.

Treatment of Colles' Fracture.—Because of its very interesting relationship to the recent treatment of fractures of the humerus by making use of the tauted periosteum as a splint an article by J. GRIFFITHS (British Med. Jour., Dec. 7, 1901) which calls attention to the application of this principle to fractured radii is of great interest. After detailing the anatomy of the part very carefully, he shows that a formerly unrecognized laxity of the ligaments of the wrist is the factor which has yielded the "give" on traction upon the open hand. To this "give" he attributes many of the failures to reduce properly and cure Colles' fracture. A very small proportion of the cases are impacted. This ligamentous laxity allows of so much "give" that in a median anterior-posterior section through the forearm and hand it amounts to more than a third of an inch. Further traction upon the living hand sets up a state of contraction in both flexors and extensors which it is very difficult to overcome and which is often mistaken for impaction. The attachment, the length and the strength of the posterior ligament of the wrist is of great surgical import in this new method of treating Colles' fracture. It corresponds to the untorn periosteum which splints the humerous when fractures of this bone are treated by the method of hyperflexion at the elbow, and seems to be the most important factor, not alone in effecting reduction but in holding the fragment in place. It resolves itself then to this, that the treatment consists simply in making the posterior ligament tense. The normal hand inflexion is carried slightly to the ulnar side. In making his splint (which is best built of copper-nickel, as this weighs but six ounces) the author allows for this deviation and carries the metal anteriorly from just below the elbow to the web of the fingers. This is held in place by three leather bands, so that at all times the parts are open to inspection. The splint can be readily adjusted to fit any adult forearm, so that it is not an expensive mode of treatment. The best results have been obtained by continuous immobilization without massage for four weeks. At the expiration of this time the movements at the wrist are free in all normal directions and the deformity is scarcely appreciable.

Intra-articular Osteochondroma Producing Ankylosis of the Knee; Operation; Recovery.—Radiography proved decidedly useful in a case of osteochondroma reported by MENCIERE (Le Prog. Méd., Nov. 30, 1901) showing the cause of ankylosis of the knee in a vicious position to be an intra-articular tumor which was independent of the great bones entering into the

formation of the knee-joint. The character of the growth being known, it was possible to determine in advance the various steps of operative procedure. Ablation of the tumor was practised without any injury to the function of the quadriceps extensor; the restoration of the power of flexion and extension followed. The writer is unable to find any previous record of a case of intra-articular osteochondroma affecting the knee-joint.

Symptoms and Treatment of Movable Kidney.—A certain degree of mobility is natural to the kidney, although the contrary might be inferred from many writings on the subject. H. MORRIS (The Lancet, Nov. 30, 1901) regards a kidney as abnormally movable when the lower half of the organ or more than the lower half so descends during deep inspiration that it can be felt between the fingers of the two hands. In extreme cases the organ can be retained between the fingers so as to prevent its return to its original position during expiration. The only justifiable operation is nephropexy, and this writer would advise operation when the symptoms are severe and are not relieved by rest, mechanical appliances and appropriate medicinal and dietetic treatment. Morris believes that belts and pads are useless in uncomplicated nephroptosis, although they may have some value in the rare cases in which movable kidney is associated with enteroptosis. He attaches no value whatever to rest in the recumbent position, having tried this treatment without result for six or nine months in cases afterward relieved by operation. The average mortality of nephropexy is slightly over 1 per cent. Nephropexy has cured 90 per cent. of the cases in which pain was the leading symptom; it has been less successful when performed mainly on account of flatulent dyspepsia and constipation, and is not at all satisfactory in cases presenting nervous symptoms chiefly. If hysteria or neurasthenia is clearly secondary to a movable kidney, Morris would perform nephropexy after trying palliative means, but would warn the patient or her friends of the speculative nature of the result. When renal crises are a feature of the case, prompt operation should be urged because of the constant risk of hydronephrosis and recurrent pain. When a movable kidney gives rise to no inconvenience, operation ought not to be thought of and a belt need not be worn.

Subphrenic Abscess After Appendicitis.—Probably no other disease has commanded such thorough discussion as appendicitis, but latterly its complications, immediate and remote, are demanding attention. C. A. ELSBERG (Ann. of Surg., Dec., 1901) discusses the relation between appendicitis and subphrenic abscesses. This condition rests upon the following symptoms: Pain located in the right hypochondrium, of sudden or gradual onset, slight and increasing or intense from the beginning, localized between the eighth and eleventh ribs and the mammary and posterior axillary lines or in the right scapular region. The hepatic region shows fine friction râles, dulness and flatness extending from day to day and finally overreaching the normal hepatic dulness. Displacement of the liver downward is usual later in the disease. Gas in the abscess obliterates the hepatic dulness. The differential diagnosis between this condition and pleurisy with effusion rests on these facts: Pleurisy begins with signs of affection of the chest, rapid respiration, cough, expectoration and shows a level of dulness concave upward and changing with the position of the patient. Subphrenic abscess, as such, has no chest signs and the level of dulness is either horizontal or convex upward and fixed without reference to position. Pleurisy has breath and voice changes, which are absent with the abscess. The liver is always depressed downward by abscess, rarely by pleurisy unless excessive. The heart is displaced by pleurisy and the chest bulges, but not by abscess. If both these conditions are associated great difficulty in diagnosis arises. The history and the aspirating needle may establish the diagnosis. When perforation of the diaphragm occurs in abscesses it is usually accompanied by the sudden onset of pain and by signs of fluid in the chest. Litten claims that a well-marked, depressed, undulating curve visible in the side of the thorax during inspiration and a convex prominent line moving upward during expiration are pathognomonic. Owing, however, to the necessary fixation of the diaphragm, this sign is not reliable, as is also one described by Fürbringer, who stated that a needle passed into the abscess cavity during inspiration and expiration would move in the opposite direction to that it would take if in the pleural cavity. The differential diagnosis between subphrenic and hepatic abscess is very difficult, sometimes impossible. In both dulness is increased upward and downward; in both breathing is heard above the level of the dulness and in both the clinical symptoms may be the same. Hepatic abscess is, however, the more rare after appendicitis, presents pain in the right scapular region more frequently, paralysis of the diaphragm less frequently, chills with profuse sweating oftener and to a greater degree. The pus from abscess of the liver is always very different, being as a rule full of liver cells, chocolate-colored and with little or no odor. Pus from a subphrenic abscess, on the other hand, is almost always foul owing to the source of infection in the intestines.

Osteomalacia.—An interesting case in which castration is reported to have effected a cure is quoted by HOLLANDER (Deut. med. Woch., Nov. 28, 1901). His patient was an unmarried woman, subject for ten years past to chronic rheumatism. To this was added later on interference with the motor functions. Examination showed a depression of the lumbar part of the spinal column into the pelvis to such an extent that the last pair of ribs were below the brim. A double ileo-psoas paralysis resulted from the changed relations of the points of origin and insertion of the muscles, this also preventing abduction of the thigh. Electricity and drugs failed to give any relief and as a last resort castration was done. The results were marked, the severe pains ceased; in two weeks the patient could walk about with the aid of a cane and in six months very little interference with locomotion was apparent.

Surgical Treatment of Chronic Nephitis.—Just as the operation for cirrhosis of the liver was discovered by accident while operating upon supposed cases of tuberculous peritonitis and by chance causing an omental anastomosis, so is the operation for chronic nephritis now advised after successful results have been obtained in cases which were originally operated upon for simply movable kidneys. G. M. EDEBOHLS (Med. Rec., Dec. 21, 1901) reports eighteen cases of chronic nephritis which have been operated upon by him, in the first five of which operation was done in spite of the nephritis and for serious symptoms of nephroptosis rather than with any idea of benefiting the parenchymatous condition. The marked improvement of the renal symptoms, however, led to investigation and many subsequent operations have been done for the single indication of Bright's. Edebohls' operation for nephropexy consists in an exposure of the kidney by a posterior incision down to that organ, entirely freeing it from the fatty capsule and exposing it upon the posterior surface of the back. An incision is then made through the capsule from pole to pole along the external border and the capsule is stripped carefully from

the surface as far around toward the pelvis as possible and excised. The kidney is then replaced and adhesions are soon formed between its surface and the surrounding fatty capsule. The explanation for the improvement in the nephritic symptoms is that anastomoses are soon formed between the blood-vessels of the kidney and the surrounding tissues and the blood supply of this diseased organ is thereby increased. The author's experience with these cases leads him to say that he is now prepared to operate upon any patient with chronic Bright's who has no incurable complication or one absolutely forbidding the administration of an anesthetic and whose probable expectation of life is not less than a month. The latter proviso is made in view of the fact that the beneficial effects of the operation can scarcely become operative in less than ten days.

Surgical Treatment of Pelvic Suppuration.—Various applications to the cervix can hardly do harm and certainly do no good in this condition. If after a fair trial of other and better medical means the inflammation either progresses or remains stationary the aid of the surgeon must be sought. J. L. FAURE (Gaz. de Gyn., Oct. 15, 1901) enumerates the following as the proper surgical procedures: Dilatation of the cervix with prolonged drainage is the simplest method and should always be tried in mild cases. Its precise method of action is not understood, although the softening of the uterine tissue and the diminution of resistance at the mouth of the womb with a restitution of an anteflexed organ may be some of the factors which are at work. Curetting may often benefit some cases but often aggravates others. The disturbance of the uterus is so great that in acute cases with active symptoms it had best be omitted. Catheterization of the tubes was once a fad. It is self-evidently a dangerous and uncertain treatment. Simple incision and drainage of the collection of pus is in a large number of cases a most favorable step, especially when the drainage is made perfect from the outset and kept so. Extirpation of the deceased adnexa is a more radical and, in selected cases, a well-advised move. Hysterectomy is the final degree of radical measures whether of the vaginal or abdominal route. Both methods have their advantages and each its own indications. The vaginal route is without visible scar and without much tendency to hernia and usually with good drainage. It may be advantageously applied to the less extensive cases. Abdominal hysterectomy possesses the great advantage of a wide free field of operation and should be resorted to when the disease is advanced above the plane of the true pelvis. Such are the methods of approaching suppurating inflammations. Such as are non-suppurating belong in a class by themselves and are usually later in coming to operation. The point for deciding when to interfere is that of pain. Often a large mass may be carried in the pelvis, if not purulent, without much harm, but, if pain or other symptoms are caused by it, the comfort of the patient will be profoundly affected and an operation will be necessary.

Radioscopy and Bone Disease.—Many limbs have been sacrificed by unnecessary, and many lives lost by deferred, amputation on account of errors in diagnosis. Radioscopy is not a substitute, but a valuable adjunct to the well-tested clinical methods of diagnosis, says C. BECK (Ann. of Surg., Dec., 1901). His chief points are that, if with this means of examination, obscure swelling of a joint shows no impairment of its integrity, ostitis, tuberculosis, syphilis or injury can be excluded. A light shade in the midst of the deep shadow of the bone cortex is shown by abscesses beneath the periosteum or within the medulla; increase or change in shadow by necrosis and very late stages of inflammation; integrity of the articular outlines by acute rheumatism and other acute inflammation early in their course; irregular articular outlines by chronic rheumatism; sharp outlines and deep shadows by arthritis deformans according to the amount and density of the bone-deposit; loss of joint and bone outline, cloudiness and roughness, by tuberculosis in its early stages; translucency by cheesy foci; loss of bone cortex shadows by the last stages and deep shadows of the calcareous degeneration; fine spiculated trabeculæ radiating from the surface by the periosteal sarcoma; absence of the shadows of bone tissue by a myelogenous sarcoma; a strange mixture of light and dark shadows by the alveolar sarcoma; apparent integrity with an undefined affection of the medulla by aneurism; irregularity along one side of the bone by chronic osteoperiostitis; large ossified areas at the epiphyses which should be translucent by congenital syphilis; light areas in the shaft by the insufficient calcareous deposits in syphilis; synostosis between the epiphyses and diaphyses by the excessive calcareous deposit at this point in syphilis; irregular shade foci by gummata; changes in any of the syphilitic pictures by treatment; deep shadows by some forms of cysts; shadows conforming to the shape of the bone by osteoma; absence of or variations in the normal shadow in osteomalacia; very light regular shadows by chondroma; broad heads and thick bases in the phalanges by acromegaly; hypertrophy of the epiphyses of the long bones and rich osseous proliferations with little lime salts by myxedema; absence or irregularity of shadow following the characteristic deformity by rickets; both atrophy and hypertrophy in the small bones of the hand by Raynaud's disease. In studying the diseases of the hand, forearm, foot and leg it is necessary to use soft tubes because a hard one will penetrate the deposits to such an extent that there would be too little or no impression by them of the photographic plate.

Spinal Anesthesia.—Operations have been performed in a series of forty cases after the injection of tropacocaine and eucaine A, by W. KOPFSTEIN (Wiener klin. Rundschau, Dec. 6, 1901). He finds that in the majority of cases complete anesthesia is produced from the feet upward to the navel or higher, but that with some patients strong idiosyncrasies exist, manifesting themselves in headache, vomiting, subsequent severe pain at the site of operation and even dangerous collapse. Tropacocaine alters cardiac and respiratory action much less than eucaine and the former is said to be much safer in old people and has the further advantage that it causes no fever and less intense headache. There is absolutely no way of telling in advance how the injection will agree with a patient. It is not necessary, indeed even not advisable to let the patients fast before the operation, since they react less severely with a full stomach.

Diagnosis of Appendicitis.—The leucocyte count is considered a valuable adjunct in the diagnosis of the various forms of appendicular inflammation by H. CURSCHMANN (Münch. med. Woch., Nov. 26 and Dec. 3, 1901). He sets down the following rules: In the great majority of cases the simple forms of appendicitis may be distinguished from the suppurative ones by a white-cell count, and this holds true especially where the physical signs and temperature curve are uncertain. The simple cases show an absence or only slight increase of leucocytes and their number generally falls to or nearly to normal in a few days. High counts in these cases may, however, occur in the beginning of the disease; the number, however, rarely exceeds twenty to twenty-two thousand, and if the number of leucocytes remains high and other lesions, such

as pneumonia, may be excluded, abscess-formation is almost certain. If an operation is performed, a count near the normal will soon be obtained provided free drainage takes place, even if this occurs into the rectum or some other hollow viscus. A methodical examination of the blood in all these cases is a much more trustworthy guide than the fever curve. Concerning cases in which small abscesses undergo a spontaneous cure or where perforation into the peritoneal cavity takes place, the author has no experience, but it is probable that in the latter the number of white cells rapidly sinks to or below the normal.

Accidents in Renal Surgery.—An interesting case of nephrectomy is related by H. Lindner (Münch. med. Woch., Nov. 26, 1901). In attempting to remove a large carcinoma of the kidney, the inferior vena cava was torn through, owing to the close connection of the tumor with this vessel. Clamps were immediately applied, but unfortunately the distal end was seized first, so that a large amount of air was sucked into the vessel and death occurred soon after. The author discusses the possibility of resection in continuity of the inferior vena cava and from the published cases finds that this is not incompatible with life, though most cases died soon after from other causes. Resection of portions of the vein which were infiltrated with malignant growths and subsequent suture of the vein have been accomplished with better success.

Treatment of Eroded Joints with Gold.—The distressing deformity, which always seems worse to the lay mind because of the mystery attached, attending excision of a major joint, in particular the shortening, can, according to an interesting case of C. B. Keetley (Brit. Med. Jour., Dec. 7, 1901), be entirely overcome. The treatment consists of a series of three operations: (1) Curettage, by which as little as possible of the bone is removed; (2) the insertion of a gold plate between the bones; (3) the removal of this plate. An interval of about one month should elapse between these procedures. The results of this treatment are promising. In place of the marked shortening which is so often evident in cases of tuberculous elbow in which there has been a very free removal of bone, there is here no chance whatever for shrinkage. Unfortunately, the use of gold plates is more or less limited for in a large proportion of tuberculous joints it is desirable to obtain bony union. In selected cases, however, and the greater number would be from the elbow, it is possible to get an excellent range of motion without the danger of shortening which exists in the ordinary operation. The author was brought to consider the use of gold from having frequently used it as a means of closing wide hernial openings. Occasionally, because of the nearness of the metal to the skin, it became desirable to remove it. Invariably the gold was found resting in a dense sac the walls of which were so hard and smooth as to glisten like silver. The desirability of using some absorbable metal is discussed with the conclusion that it is to be avoided, first, because the absorption must be uneven—thus leaving several loose bodies in the joint toward the end of the process; secondly, because of the difficulty of being sure just when total absorption has taken place.

MEDICINE.

Rheumatic Affections of the Throat.—For many years it has been thought that rheumatism is connected in some way with inflammation of the throat and more careful investigations seem to increase that belief. W. Cheatham (Med. Rec., Dec. 14, 1901) shows that two theories have arisen; one is that the rheumatic poison enters the system through the tonsil and the other view is that the tonsillitis is one of the rheumatic manifestations of the rheumatic diathesis. Although the germ which has been found in the blood and joints of acute rheumatic cases, and which is supposed to be the specific cause, has also been present in large numbers in tonsillar affections, yet sufficient work has not been done to enable sound conclusions to be drawn. Abrahams believes that rheumatic sore throat may be of two kinds, viz., faucial erythema and tonsillitis proper. The former is more common in adults, the latter in children. Faucial erythema is an initial manifestation of acute rheumatism, tonsilitis may be the actual initial primary lesion. Quinsy or peritonsillar abscess is the one throat lesion which does not seem to have any relation to rheumatism and is in no way influenced by rheumatic remedies. Further research is necessary to determine the form of angina which is definitely associated with rheumatism and also to discover the true cause of rheumatism.

Cause of Rheumatism.—The digestive tract has recently been held responsible for various systemic affections on account of its depraved functions and consequent auto-intoxications. M. A. H. Thelberg (Med. Rec., Dec. 14, 1901) suggests also the relation of rheumatism to the digestive tract. Immunity is due to an antitoxic substance soluble only in an alkaline medium. In rheumatism there is a decreased alkalinity due to the presence of saro-lactic acid, and the diplococcus of Poynton and Paine, which is supposed to be the specific cause of rheumatism, grows best in a medium made slightly acid by lactic acid. Prout believes that exposure to cold accounts for the increased percentage of lactic acid, while Latham suggests muscular hyperoxidation. The author of this article offers the theory that faulty digestion, assimilation and elimination, whereby the natural immunity is greatly decreased and the nerve centers made more susceptible to invitation, may be the predisposing cause, offering an excellent medium for the growth of the specific germs. Accordingly, even in acute cases he has discarded the use of salicylates and pays especial attention to the food and the treatment of the stomach, liver and intestines. He does not exclude proteids, but carefully regulates their ingestion.

Strongyloides Intestinalis in the United States.—In China and certain other countries of Asia, also occasionally in Europe and Australia, instances of intestinal infection with this parasite have from time to time been recorded. Hitherto no cases of this disease have been reported in the United States. W. S. Thayer (Jour. Exp. Med., Nov. 29, 1901) during the past three years has observed three cases which were admitted to the wards of the Johns Hopkins Hospital. The first case was diagnosed as amebic dysentery and intestinal infection with the trichomonas intestinalis and strongyloides intestinalis. The ameba coli, as well as the afore-named parasites, was present in the feces. There was also a liver abscess. This was evacuated and ameba coli found in the contents. The case proceeded to a fatal termination. The second case presented the ordinary appearances of a chronic diarrhea. Here also the strongyloides intestinalis was found in the feces. This case recovered. The third case was also clinically a chronic diarrhea. The same parasite was present in the feces as in the second case. Here the principal treatment consisted in the internal administration of tannogen, ten grains, every four hours. Complete recovery took place. In all probability these cases all originated in Maryland and Virginia. It is evident that diarrhea associated with the presence of strongyloides intestinalis occurs in the United States. As in most cases originating elsewhere in temperate climates, the development of the sexually-diffrentiated, free-living generation was in these instances apparently unusual,

the direct transformation of the rhabditiform embryos into filariform larvæ predominating. The discovery of these parasites in this country should emphasize the possibility that uncinaria duodenalis may also be present. More systematic examination of feces both in public clinics and in private practice is to be much desired.

Chronic Hyperplastic Tuberculosis of the Intestine.—During the last ten or twelve years a few writers, particularly French and German observers, have from time to time called attention to the existence of a form of tuberculosis affecting various segments of the intestinal tube and characterized by a variable, but usually a considerable degree of thickening of the wall of the intestine. A case reported by A. J. LARTIGAU (Jour. of Exp. Med., Nov. 29, 1901) is unique because of the length of gut implicated and the absence of distinct stenosis and of apparent ulceration of the mucous membrane anywhere in the intestine. The patient was a male forty-nine years of age. There was no family history of tuberculosis. About three years before his death he began steadily to lose weight and complain of fatigue. Coincidently there appeared a universal dark pigmentation of the skin. After a short time he began to suffer with cramp-like pains all over his abdomen which became periodical in character and gradually increased in severity. Vomiting occurred from time to time. No mass in the abdomen was at any time felt by the patient, but a vague sense of discomfort and heaviness was constantly present. The stools and urine were normal in appearance. There was a gradual increase in the severity of all the symptoms. The temperature became somewhat elevated, an evening rise of 1 to 2° F. being observed. Finally, some days before dissolution, right-sided lobar pneumonia appeared and death shortly supervened. At autopsy the following anatomical diagnosis was made: Hyperplastic tuberculosis of the small and large intestine; lobar pneumonia of the right lower lobe; edema of the lungs; tuberculosis of adrenals and of mesenteric lymph-nodes; acute splenic tumor; cloudy swelling of liver; slight chronic diffuse nephritis. The tuberculous process of the intestine extended from the upper third of the ileum to the sigmoid flexure. The changes were most markd in the lower portion of the ileum, the cecum and the ascending colon. The most conspicuous feature of the mucosa was the presence of numerous papillomatous masses of an average length of 4 or 5 mm. These masses consisted of an epithelial layer covering a central portion of adult connective tissue rather loosely arranged in which a moderate number of round cells were discretely spread. Numerous strands of unstriped muscle tissue were seen between these connective tissue bands. No tubercles, necrosis or giant cells were observed. Tubercle bacilli in enormous numbers were present in the epithelial layer of the lower ileum, cecum and ascending colon. In other portions of the intestine few or no tubercle bacilli were found in this layer.

Relative Importance of Muscle and Valves in Heart Disease.—Certain forms of dilatation of the heart involve dilatation of the orifices so that the murmurs produced are very loud. These, together with hermic murmurs and the anonymous murmurs heard under the clavicle and in other places, render the diagnosis of valvular disease a difficult proceeding. LOUIS FAUGÈRES BISHOP (Pediatrics, Dec. 15, 1901) believes that the important consideration is the integrity of the heart muscle, and that, when this is healthy, a moderate degree of leakage need cause no anxiety. Having detected an enlarged contour to the heart, how much is this due to thickening of the muscle and how much to overdistention of the cavities? Irregularity is not necessarily due to myocarditis; a cardiac neurosis may be combined with a slight deformity of the valves. The test is how well the heart does its work over a long period of time, and how well it stands a considerable amount of exercise.

Prognosis of Interstitial Nephritis.—The question of prognosis is often of the greatest importance in chronic Bright's disease and to this end early diagnosis and proper classification are necessary. L. BOUVERET (Wien. med. Blaetter, Nov. 14 and 21, 1901) considers three groups of cases as follows: First, those in which the subjective symptoms are slight and amount only to to a feeling of oppression and cardiac palpitation on exertion, frequent urination and perhaps attacks of coughing; on physical examination the pulse will be found to be harder and somewhat more frequent than normal, the urine is increased in quantity and of normal or slightly increased specific gravity and contains no albumin. It is especially after the chief meals of the day that the patients feel most uncomfortable. The number of such cases that come under observation is small and an actual cure is possible. Not so, however, the second class, in which the course is progressive and uremia a frequent complication. The symptoms are in the main the same but more pregnant. The hypertrophy of the heart is perceptible and gallop-rhythm occurs, while the urine is characteristic and contains traces of albumin. Death may occur in from one to two years or remissions even up to ten years are possible; the prognosis depends upon the amount of improvement which follows a trial cure consisting in absolute rest and milk diet. The third class includes all those in which, though a cure is impossible, a total standstill of the morbid process is to be anticipated. In these cases, repeated examination does not show any change, and with proper care the prognosis is good.

Carcinoma and Malaria.—Stimulated by the recent article of Loeffler, H. KRUSE (Munch. med. Woch., Nov. 26, 1901) investigated the prevalence of both diseases in the various districts of Italy with the result that the number of cases of both diseases by no means stands in inverse relation to each other, but that the frequency of carcinoma is high in those provinces where the medium height of the inhabitants is greatest, while those of small stature, brunette type, narrow head, low forehead and relatively large mouth are comparatively immune. The same may be said of those possessed of similar racial characteristics in other countries.

Epidemic of Catarrhal Jaundice.—Because of the widespread interest recently manifested in the etiology and differential diagnosis of jaundice, this account of an outbreak in Derbyshire by H. PECK (Brit. Med. Jour., Dec. 7, 1901) is of more than passing import. The epidemic occurred in a very unusually healthy region in the colliery districts, two little villages having supplied the 750 cases. The houses are of brick, but have only one door, so that the ventilation is none too good. The water supply is from a main which watered 23,000 souls. Each house has a privy. The conservancy system is in vogue and the pits, 35 to 46 feet from the houses, are regularly emptied by the company's agents. In conclusion, Health Officer Peck states that (1) the disease is probably icterus gravis or epidemic jaundice, sometimes called Weil's disease; it differs from previous outbreaks in its onset, being sometimes gradual, and in the comparatively low temperatures recorded; (2) the incubation period is perhaps six or seven days; (3) the duration from exposure to infection to commencing recovery is ten or twelve days, but the jaundice may persist; (4) the mode of infection cannot be deduced by a consideration of the cases recorded in this outbreak, but bacteriological examination might elucidate it; (5) the disease is

not due to the ingestion of food or drink; the popular impression that it was occasioned by the use of a drinking-water which was more or less heavily charged with yellow pigment is erroneous; (6) the disease is probably conveyed by individuals. There exists very definite proof that it was carried by a collier from one village to another.

NEUROLOGY AND PSYCHIATRY.

Three Cases of Family Periodic Paralysis.—In previously recorded cases of family periodic paralysis there has been no instance where the paralytic attacks have occurred before the age of six years. Three cases are reported by E. F. BUZZARD (The Lancet, Dec. 7, 1901) and in at least two of them the attacks were present from infancy. The tendency of attacks to follow hard exercise has been noticed by nearly all observers. In the cases described by Buzzard it was easy to produce attacks for purposes of observation; the paralysis only supervened, however, after an interval of rest. In characteristic attacks the proximal limb muscles are first and most often affected; those of the trunk are involved also in attacks of some degree of severity, while only in the most severe attacks are muscles affected which are supplied by cranial nerves. Examination of the patient in the intervals between attacks fails to reveal any abnormality of body or mind; a diagnosis cannot really be made without an opportunity to witness an attack. In the light of our knowledge of this disease vague stories told by a mother of a child who "falls about" or "refuses to get up" periodically should receive some consideration. In severe attacks the condition of the heart and the difficulty of respiration are sufficiently grave to make us regard every such occurrence as a source of possible danger. As yet no death directly due to the disease has been recorded. No means of alleviating or curing this disease has yet been discovered; massage, electricity and strychnine have been used for many months without success. What is needed is a knowledge of the pathology of the disease: as yet we have only conjectures.

Case of Asthenic Bulbar Paralysis (Myasthenia Gravis.—The pathology of the various forms of bulbar paralysis is now fairly well understood. "Asthenic" bulbar paralysis is an exception; no lesion has yet been found to acount for this disease, and W. K. HUNTER (The Lancet, Dec. 7, 1901) raises the question whether the condition should not be regarded as a general myasthenia especially affecting the muscles supplied from the bulb. This writer reports the case of a man of 58 who experienced at first difficulty in speaking and swallowing, together with intermittent weakness in the extensor muscles of the neck. There was no family history of nervous ailment. The patient's head would fall forward on his chest unless he prevented this by supporting the forehead with his fingers. There was no spasm of the sternomastoids; the trouble was evidently in the trapezius and erector spinæ muscles, and there was some wasting of the upper fibers of the trapezius. At times there was spasm of the metacarpo-phalangeal joints of the right hand. The patellar reflexes were unduly active, but neither knee clonus nor ankle clonus could be obtained. Sensation was normal in the arms and legs; visual acuity was normal and there was no contraction of the fields of vision. The pupils were equal and responded to light and accommodation. Heart, lungs and kidneys were healthy. Articulation and deglutition grew steadily more difficult; myasthenia invaded the arms and later the legs. Attacks of dyspnea occurred two months after admission and the third of these attacks ended fatally. Postmortem the brain and cord presented to the naked eye perfectly healthy appearances. Sections of the pons, medulla and cord were stained by Weigert's method, Nisl's method and with hematoxylon and eosin. No degenerative change was found in any of the sensory or motor tracts at the different levels, or in the anterior or posterior nerve roots. The sections stained with hematoxylon and eosin showed colloid changes in the vessel walls. The peripheral nerves and the muscles were not examined histologically.

THERAPEUTIC HINTS.

Alopecia Areata.—Shampoo the region every day, then bathe with carbon tetrachloride, which removes grease and micro-organisms, and rub in with slight friction:

℞ Hydrargyri bichlor..... 0.90 (gr. 14)
Camphor ..... 60.0 (℥ij)
Spt. terebinth..... 60.0 (℥ij)
Spt. lavand ..... 30.0 (℥j)
Alcohol .....300.0 (℥x)

The neighboring parts should be depilated and touched with a pencil made of

℞ Sulphur precip..... 0.50 (gr. viij)
Resorbin ..... 1.50 (gr. xxiij)
Chrysarobin
Paraffin, aa..... 2.50 (gr. xl)
Ol. theobrom..... 3.50 (gr. lv)

Or a cotton roll dipped in strong carbolic may be laid on until the parts are blanched, when further action of the carbolic is stopped by applying pure alcohol.—M. H. HALLOPEAU. in Bull général de therapeutique, Nov. 15, 1901.

Tuberculosis in Childhood.—The importance of diet becomes greater the younger the victim, and the necessity for artificially feeding infants complicates the problem. In cases under a year old, B. K. RACHFORD (Archives of Pediatrics, Dec., 1901) begins by feeding Nestlé's food alone, and when the stools become normal adds cod-liver oil, pure or in emulsion, to several of the feedings each day. As the patient's condition improves, he gradually substitutes modified cow's milk. He also adds the white of one egg to one bottle of the food, and the yolk of an egg to another. In older children milk and cod-liver oil are the staples, and fresh eggs, good beef and poultry, cereals, fresh fruits, and well-cooked vegetables may be added as age permits. Fresh air and sunshine should be obtained for as much of the day as possible. He uses the following inunction:

℞ Guaiacol 3j
Lanolin .....℥ij
Lard .....℥v

M. Sig.: One level teaspoonful to be rubbed into chest daily at bedtime. This may be applied also over tuberculous lymph-nodes or over the abdomen in tuberculous peritonitis. The carbonate of guaiacol may be given internally, though creosote is preferred. Creosote may be given in capsule or by inhalation.

℞ Tinct. gentianæ.....(℥iss)
Creosote .....(℥ss)

M. Sig.: Three to five drops in a capsule and take every six hours, followed by a drink of milk.

℞ Tinct. opii camph.....℥ij
Creosote .....℥ij
Alcohol .....℥iv

M. Sig.: Five to fifteen drops in creosote inhaler; use fifteen minutes three times a day. The iodide of iron, arsenic, and malt containing diastase, may each have their indications.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JANUARY 4, 1902.

THE NICARAGUA AND PANAMA CANALS.

THE article which is printed elsewhere in this issue on sanitary aspects of the Nicaragua and Panama canals calls attention to a timely and important subject which until now seems to have received but a small share of attention. All are agreed that probably the greatest problem to be faced in constructing the canal is to obtain a sufficient number of laborers and maintain them in a healthful and efficient condition. Yet in the canal discussions which have found their way into print, the question of health has generally been dismissed with but little more than the mention of its importance. To this curiously inconsistent practice even the report of the Trans-Isthmian Canal Commission now before Congress offers no exception. Special interest therefore attaches to the article by Dr. George A. Soper, a specialist in sanitary matters, in which the health conditions which would probably surround the two canals during construction and afterward are very fully and impartially discussed.

Probably no other country which has enjoyed so large a share of public attention bears such an evil reputation for insalubrity as that part of the western continent in which the two canal routes are located. More or less has been known about Central America for four hundred years, yet from the time of the fourth voyage of Columbus, when the country was discovered, up to the present time no credible person has presumed to give the Isthmus a clean bill of health. On the contrary, the experience of sickness and death connected with Central America has earned for it such titles as the "Pest House of the Tropics" and the "Grave of the European."

The habits of the people of the Isthmus render them peculiarly liable to disease, for they are careless of exposure and indiscreet as to diet. Foreigners seldom, if ever, attain the same degree of immunity from disease as that enjoyed by the natives. Of the former, the type which is most suited to endure the hardships of the Isthmian climate is a slender, dark-complexioned man of thick skin; abstemious habits are of great advantage to those who visit the country. No one should engage to work in this region who is not of sound body and mature age.

The construction of a canal across the Central American Isthmus is not free from elements which make the business of protecting the health of those engaged upon the work especially difficult. The sanitary care of an army of soldiers under strict military discipline, in this region, unencumbered by the exhausting labors of digging and building a canal would be a large undertaking. But if we add to the natural disadvantages of climate and topography the stupendous engineering work contemplated, involving an estimated expenditure of nearly 200,000,000 dollars and the continuous employment of ten or fifteen thousand men for eight or more years, it will be seen that the Government has a problem in hand which calls for all the knowledge of hygiene which can be brought to bear upon it.

Nor does it appear that this, our substitute for the old Northwest Passage, is less dangerous to navigators. It is not improbable that more or less apprehension will always be felt that ships passing through the canal will become infected by diseases indigenous to the country, or carried there by vessels from unhealthy ports. Will the Isthmian canal become a focus of disease as well as a focus of trade?

It is not assumed here that a lax sanitary control is a part of the nation's program, nor that the canal would long be permitted to remain a focus of disease should it ever gain that undesirable character. Yet the good faith of those entrusted with the responsibility of setting the project on foot should not be accepted as a guaranty that public health at the canal will al-

ways be efficiently protected. In matters of hygiene the human race is prone to carelessness and unaccountable oversight, and it would not be beyond the range of possibility if plague, pestilence and disease, always the best and too often the only teachers of sanitation, should be needed to point out the necessity of adequately providing for the avoidance of diseases. If the awful history of disease connected with the building of the Suez Canal, Panama Railroad and Panama Canal is not to be repeated, sanitary measures on a scale and of a completeness heretofore unknown in public works will require to be undertaken.

As to a choice between the Panama and Nicaragua routes, a review of the conditions along the two lines can lead to but one opinion. The Panama route is much to be preferred from the standpoint of health. At Panama the seasons are divided into wet and dry periods, as is common in the tropics; there is nothing abnormal in the precipitation or temperature. For four months of the year the weather is clear and practically cloudless. Along a large part of the Nicaragua route there is no dry season. Rain falls day or night and often for days and nights together. The rainfall is distinctly abnormal at Grey Town. The records of precipitation here are the heaviest yet reported for any point on the American continent. The fall of rain for the year 1900 was over 266 inches and has often been in excess of that figure. Over 12 inches of rain have been known to fall in twenty-four hours.

It has been stated that the Nicaragua route has a better history of health than Panama, but any argument which seeks to use the past history of the two routes as an indication of future conditions is specious and misleading. We might almost say that the Panama route is the only one which has a history. Since early in the sixteenth century Panama has been a favorite route for travelers between the Atlantic and Pacific Oceans; nearer our own time, probably more people went to and from California during the gold fever than across the continent in any other way; the Panama Railroad has been in existence for fifty years, during which a vast amount of traffic has passed over its rails; the extensive works of the Panama Canal Company are here. During all this time the Nicaragua route was a wilderness, imperfectly explored.

The health of those employed in constructing, as well as those who will subsequently use these waterways, is an element of superlative importance and one that cannot be neglected when Congress undertakes the consideration of this great engineering problem.

THE CRIMINAL, CZOLGOSZ.

In the current number of the Medical News we present to our readers a full report of the trial, execution, autopsy and mental status of Leon F. Czolgosz, the assassin of President McKinley, together with a report of the anatomical measurements made during life by the Bertillon system, and of the postmortem findings, including anatomical measurements of the head, face, skull, etc., also a graphic anatomical description of the hemicerebra, with plates of the drawings and of photographs—full face and profile—of a postmortem plaster cast of the head, which altogether present a very comprehensive study of the physical, mental and moral status of the most remarkable criminal magnicide of the age.

The joint report of Dr. Carlos F. MacDonald and Mr. Spitzka, aside from its historic importance, is replete with interest to the medical jurist and forms a valuable contribution to the study of criminal psychology. The report is also of interest, negatively, to the psychopathologist as showing that the assassin, Czolgosz, was neither a lunatic nor a so-called degenerate. On the contrary, his history and all the facts in the case, as stated, make straightway for sanity and full responsibility for his act. Moreover, it is gratifying to note that all of the mental experts who examined Czolgosz—three for the people and two for the defence—one of the latter having been selected by the Bar Association with special reference to his competency—agreed unanimously that he was sane and responsible, thus leaving no room for reasonable doubt respecting his mental status. Surely the snap diagnosis of insanity which has already been gravely proclaimed in certain quarters, and which necessarily is based only on exaggerated and sensational newspaper reports, should have no weight against the opinions of the official, and presumably competent, experts, based on personal examinations of the culprit and accurate knowledge of all the facts and circumstances in the case, opinions that are fully sustained by the postmortem findings.

MATHEWS' COLLOIDAL THEORY.

On December 31st Dr. A. F. Mathews, Professor of Physiological Chemistry at the University of Chicago, in a paper read before the American Physiological Society, which was in annual

session in his city, presented a theory of nervous physiology that is of much more than ordinary interest. From the scant and perhaps not altogether reliable knowledge of Professor Mathews' theory which has come before us, we are impressed with the ingenuity and importance of this contribution even though a small part of what the author claims for it shall ultimately find general acceptance among neurological physiologists and pathologists.

The basis of his conception is fairly stated by the author in the three following paragraphs. The remaining eleven of the fourteen heads under which he has given a summary of his discovery to the lay press may be considered in a degree as corollaries.

"First.—Motor nerves contain or consist of a colloidal solution, the colloidal particles of which carry positive electrical charges.

"Second.—Nerve-protoplasm is stimulated by the passage of the colloidal particles from a condition of a solution to that of gelation, or jellying.

"Third.—This change is brought about by the action of ions, electrically charged atoms or groups of atoms, which bear negative charges. The stimulating action of any chemical compound depends on these negative charges. These ions (anions) having one charge, are less efficient than those with two or three. In other words, the stimulating action of any ion is proportional to the number of negative charges it bears."

These motor nerves or any other nerves are not so simple as the foregoing might lead us to believe. They consist of different organic substances, or tissues, which have different functions —the connective tissue sheath, the myelin substance, medullated nerve fibers, which surround the neuraxon. The neuraxon again consists of a ground substance in which lie the fibrillæ that carry the nerve impulses. These fibrillæ are so small that they are scarcely visible under a very high power lens. That these fibrillæ consist of a colloidal solution and carry positive electricity is a deduction very difficult of proof.

In the absence of any knowledge of the experimental research by which Professor Mathews arrives at his conclusions we must confess that they appear to us quite hypothetical and, we suspect, are based upon observations made upon bodies less complex in their chemical structure than are the nerves. It will be exceedingly interesting to learn how he has overcome the great variety of physical and chemical difficulties that surround investigations in this field, and it remains to his colleagues to decide whether or not his methods have always been so perfect as to render his deductions conclusive.

We hope to present to our readers in an early issue a complete review of Professor Mathews' theory based upon information coming through more scientific channels than the lay press.

IMMUNITY AND AGGLUTINATION IN TUBERCULOSIS.

THE relations existing between agglutination and immunity have given rise to much controversy and a vast amount of experimental research. At the present time this question has by no means been solved.

It is probably true, however, that the majority of observers are agreed that in most infections the agglutinative power of a serum is no criterion of the degree of immunity present. Without doubt the major portion of the work which has been done along these lines has been confined to observations of typhoid infection and the conclusions drawn have very largely been limited to such.

Hitherto but little investigation has been given to the agglutination of the bacillus tuberculosis. This is principally due to the fact that much difficulty has been encountered in the mode of preparation of these bacilli, so that they can be advantageously used in such work. Although Arloing and Courmont have given exhaustive directions by the means of which tubercle bacilli may be brought into a suitable condition for this test, other observers have failed by the use of their methods to obtain altogether satisfactory results. For this reason the method recently devised by Robert Koch (*Deutsche med. Wochenschrift,* Nov. 28, 1901) is deserving of special mention. By its use the author has obtained results which if confirmed are far reaching in their significance and of great importance to the clinician in his daily contact with tuberculous diseases.

At the outset it can be stated that the agglutination reaction is of no value as a means in the diagnosis of tuberculosis. Observation has shown that normal human serum in a fairly large proportion of cases contains substances which bring about the agglutination of these microorganisms. Many cases of tuberculosis fail to show a positive reaction. Animal experimentation has demonstrated the fact that so far as tuberculosis is concerned increased immunity in the majority of cases is accompanied by an increased intensity of the agglutinative power of

the serum. Koch by an application of the methods employed in his work upon animals to 74 cases of human tuberculosis has shown that a like condition of things exists in man. As a rule tuberculous subjects who are treated with a series of increasing inoculations of tuberculin show marked increase in the agglutinating power of their serum. Those cases which at the beginning give no reaction or only one in a 1 to 10 dilution by such treatment frequently give a positive result in 1 to 25 and 1 to 50 dilutions. Occasionally very high values are thus obtained. In nineteen of the 74 cases observed positive reactions were subsequently obtained with from 1 to 100 to 1 to 300 dilutions. Coincident with the increase in agglutinative power the clinical symptoms improve. The appetite and bodily weight increase, the temperature diminishes, the cough is lessened in severity and oftentimes the bacilli disappear from the sputum. If at any time during the treatment the immunizing inoculations are discontinued the agglutinating power of the serum falls and the clinical symptoms increase in severity. It is to be remembered that those most suitable for this treatment are patients in the primary and secondary stages of the disease. In no case observed was the subsequent course of the disease unfavorably influenced by this treatment. The existence of high bodily temperatures does not contra-indicate its use.

Whether the results obtained by Koch in the employment of this treatment are to be substantiated by other observers remains to be seen. However this may be, it would appear that, as far as tuberculosis is concerned, the important fact has been established that intensity of agglutination and degree of immunity stand in direct relation to each other. In the judicious handling of tuberculous patients a cardinal point for the clinician to establish is the degree of immunity which the individual possesses to the existing process. Upon this fact depends in a large measure the subsequent management of the case from climatic, therapeutic and prognostic standpoints. Any method by which such can be established is of incalculable value. The further confirmation of the results obtained by Koch will be awaited eagerly by the profession at large.

ECHOES AND NEWS.

NEW YORK.

Lunacy Commission Complete.—By the appointment of ex-Judge Daniel N. Lockwood of Buffalo, formerly a Representative, as a member of the State Commission in Lunacy, that body is once again complete as to membership. The Commission has the power to investigate the condition and administration of the public and private insane asylums and institutions of the State, as well as the treatment of patients in them. The Pathological Institute, which is now in course of reorganization by the new director, Dr. Meyer, is also under the Commission in Lunacy. There will be a meeting of the latter in Albany next Monday to map out the winter's work.

An Old Tapestry for a Hospital.—For the new French hospital which is to be built at Nos. 450 to 456 West Thirty-fourth Street, the French Government has contributed $20,000, together with a valuable Gobelin tapestry, from the painting by David representing Napoleon by Jaffa. It is valued at $50,000, and is to be sold for the benefit of the building fund. The site and building of the present hospital at No. 320 West Thirty-fourth Street have already been sold, and the new hospital, which is to cost $250,000, will be built by the French Benevolent Society. It will embody many French ideas in furnishing and equipment that are new to Americans. One of these will be a completely isolated ward for consumptives on the top floor. The structure will be seven stories high and built of red brick and limestone. Its frontage will be eighty-four feet and its depth ninety-eight feet.

Microscope Stolen.—At some date between the 20th of November and the 26th of December last a Leitz microscope, No. 34,515, with three objectives, Nos. 25,607, 11,207 and 11,235 respectively, was removed from the Bacteriological Laboratory of the New York City Board of Health. Should this instrument or its lenses come to the notice of a reader of this he is requested to treat with the person who presents the goods without arousing his suspicion and immediately notify Captain Titus of the Detective Bureau of New York.

Cause of Prevailing Destitution.—In explanation of the marked increase in the applications for aid received during the last four or five weeks officers of the different charitable societies in this city said recently that it was due partly to the earlier advent than usual of the cold weather, but more particularly to the prevalence of infectious and contagious diseases among the poor. The reports of the Department of Health for the last five weeks show a really startling increase in diphtheria, measles, scarlet fever, and croup, the diseases that find most favorable conditions among the children of the poor. Among contagious and infectious diseases the Health Board also places phthisis, smallpox and typhoid and typhus fevers, but all of these four show a considerable falling off as compared with the last few months, so that the first four named are alone responsible for an increase of nearly 100 per cent. in the last nine weeks. For the week ending December 7th there were 1,406 cases of contagious diseases reported, while for the week ending October 19th there were only 702. These are the extremes in this period of time. The last week in October showed a total of 780, successive weeks showing this increase: 838, 904, 1,045, 1,091, 1,214, 1,406, and 1,365. For the week ending October 10th there were reported 56 cases of measles. Week before last there were no less than 596. With such a sick-rate increase as this the wonder is that the applications for help are not greater than they are.

New York Academy of Medicine.—On January 2d the annual meeting of the Academy of Medicine was held. The annual reports were read as usual, delegates to the New York State Medical Society were elected, and the Symposium on Tuberculosis was continued from the last meeting. Drs. Peabody, Knopf,

Meyer, Loomis and others discussed the general subject and particularly emphasized the need of sanatoria for the care of the tuberculous.

Dr. Carr Injured.—While alighting from a moving street-car on December 30th, Dr. Walter Lester Carr slipped and broke his leg. By the time surgical assistance arrived Dr. Carr had made a diagnosis and by means of his dismantled umbrella had applied an effective temporary dressing. He was removed to the New York Hospital, where he now awaits the repair of his fracture.

PHILADELPHIA.

Census of the Blind in Philadelphia.—A police census of blind persons in this city has lately been made at the instance of the Pennsylvania Home Teaching Society and Free Circulating Library for the Blind. It shows that there are 352 blind persons in the city, 111 of whom are in institutions for the blind. The report is believed to be accurate for all but four of the police districts.

Smallpox in Philadelphia and Camden.—For the week ending December 28th there was a slight increase in cases in both cities. In Philadelphia there were reported 79 new cases and 19 deaths, an unusually large mortality. Free vaccination is to be offered to residents of Camden by house-to-house canvass. The isolation hospital is overcrowded and many patients are quarantined in their homes. Fumigation of all of Camden's mail is being considered by the Board of Health.

Unveiling of Tablet to Dr. Wilson.—On December 28th a tablet to the memory of Dr. Charles Meigs Wilson was unveiled at the Philadelphia Lying-in Charity at Eleventh and Cherry Streets, the tablet being a memorial from the nurses who received their instruction under Dr. Wilson when he was in charge of the hospital from 1884 to 1890. It was largely through Dr. Wilson's efforts that the present large building was erected and he was the organizer of the first class of nurses in 1886. He died in 1891.

Hospitals May Receive Aid from Carnegie.—The local district of mine-workers at Pittsburg have recently been endeavoring to interest Andrew Carnegie in the establishment of a hospital for working-men. In a letter to their president Mr. Carnegie states that he has "often thought upon the hospital question. The first difficulty is to find a central place which all could reach; second, to maintain a first-class institution where its patients are limited to injured workmen. It seems to me that the best plan might be found in arranging with several of the hospitals for a working-men's ward, to which any workman injured in mill or mine would have a right to be sent and all expenses paid. The injured men could then be sent to the hospital nearest or best fitted to render aid." Mr. Carnegie promises attention to the question when he visits Pittsburg in the fall.

Can Osteopaths Legally Vaccinate?—The question of osteopathic practise has arisen at Ashley, Penn., in connection with the compulsory school vaccination act. Upward of three hundred school children were vaccinated by osteopaths because their charges were less than those of regular practitioners. The School Board holds that as osteopaths have no legal standing their certificates are of no value and as a consequence the children may be refused entrance to school.

Meeting of American Chemical Society.—As this is being written the American Chemical Society is holding its twenty-fifth annual meeting in this city. The Society now has 1,933 members. Among the papers of medical interest are "The Presence of Arsenic in Chemicals and Food-Products and the Efficiency of Several Arsenical Methods," by Lyman F. Kebler; "Aqua Ammonia; Its Impurities and Methods of Analysis," by J. D. Pennock and D. A. Morton; "Improved Forms of Apparatus for Water Analysis," by George E. Thomas and Clarence Hall; "The Sterilization of Water by Peroxide of Chlorine,' by George A. Soper. The address of the President, F. W. Clarke, was on "The Development of Chemistry."

Marine Hospital for Pittsburg.—Congressman Dalzell has introduced a bill appropriating $100,000 for erecting a marine hospital at Pittsburg.

CHICAGO.

St. Luke's Hospital.—The thirty-eighth annual report of this hospital has just been issued and is gratifying to the Board of Trustees, inasmuch as more work has been done in the institution than in former years, and yet expenses have been kept within the income. The number of patients treated was 1,818, and 36.2 per cent. of the cases were taken care of without cost to the patient. The training-school for nurses connected with the hospital is in a flourishing condition.

Improvements.—Many improvements have been made during the year in the hospital and the building is in better condition than ever. William G. Hibbard has built a smoking-room, connected with the Hibbard Surgical Ward. The nurses in their limited hours of spare time gathered material for a fair, which was held on April 18th, in the Nurses' Home. They realized $1,080.00, which they devoted to the current expenses of the hospital.

Finances of the Hospital.—In commenting on the finances, the report contains the following by the Trustees: "The financial statements show the healthy condition of the hospital finances. The total receipts were $100,293.00 and the expenses amounted to $99,899.00, leaving a balance of $394.00 on hand on October 1st. The policy of keeping the expenses within the receipts has been rigidly and successfully adhered to through the year It is undoubtedly the only course to follow, but the Trustees are constantly reminded of the suffering that could be ministered to if the supply of current funds were larger. Every additional dollar received over the present income would enlarge the charitable work."

Statistics of Patients.—The number of patients treated in the hospital during the year is less than last year, but the number of patient days, which represents the amount of work done, is considerably larger. The cost per patient per day has been reduced without injury to the service from $1.85 to $1.80. The in-patient free work amounts to 36.2 per cent. of the whole. In addition must be taken into account a considerable number of patients who are admitted and counted as pay patients, but who are unable to keep up their payments. Again, the accident ward cases are, with few exceptions, treated without charge. The patients treated in the dispensary are wholly free so far as the treatment is concerned. It may therefore be safely estimated that the free work of the hospital is not less than 45 per cent. of the whole.

Lowest Death-Rate on Record.—With the few days remaining to round out the first year of the new century, a total of 23,625 deaths had been recorded up to the close of last week by the Bureau of Vital Statistics of the Chicago City Health Department. At this rate, the total mortality of 1901 will not exceed 24,300, and, figured on the minimum mid-year population as given by the United States Census Office. 1,758,000, the annual rate per one thousand will be about 13.8, the lowest ever recorded for this or any other city of more than one million population. The

lowest previous rate, based on the United States Census figures of population was 14.36 per one thousand in 1897. For the previous ten years, 1890-1900, the average mortality-rate was 17.87, or nearly 22 (21.8) per cent. higher than this probable rate for 1901.

Western Surgical and Gynecological Association.—The eleventh annual meeting of this Association was held at the Great Northern Hotel December 18th and 19th under the presidency of Dr. A. F. Jonas, of Omaha, Nebraska. The meeting was well attended. The papers were of a high order and some of the discussions very animated. The following officers were elected for the ensuing year: President, Dr. James E. Moore, Minneapolis, Minn.; First Vice-President, Dr. J. R. Hollowbush, Rock Island, Ill.; Second Vice-President, Dr. W. W. Grant, Denver, Colorado; Secretary-Treasurer, Dr. George H. Simmons, Chicago, Ill. St. Joseph, Mo., was selected as the place for holding the next annual meeting; time, December 29 and 30, 1902.

Diphtheria Statistics.—Diphtheria has claimed the fewest number of victims in the year just closed of any in nearly a quarter of a century, notwithstanding a four-fold increase of population during the period. Between 1879 and 1900 inclusive there were 19,002 deaths recorded from this disease—a yearly average of 864, with the lowest number 531 (in 1883) and the highest 1,420 (in 1895), in the fall of which year the antitoxin treatment was begun by the Health Department. There will be less than 500 diphtheria deaths this year.

CANADA.

Appointment.—Dr. J. Alexander Hutchinson of Montreal, Chief Surgeon of the Grand Trunk Railway in Canada, has lately been appointed surgeon-in-chief to the Central Vermont Railroad.

Hospital Destroyed.—The general hospital at Mattawa, Ontario, was burnt to the ground on December 17th. There were no fatalities.

Montreal Medico-Chirurgical Society.—The following officers have been elected for the current year: President, Dr. George E. Armstrong; First Vice-President, Dr. H. S. Birkett; Secretary, Dr. Alfred T. Bazin; Treasurer, Dr. Jack; Trustees, Drs. Perrigo, G. A. Brown and F. J. Shepherd.

Quebec Doctors Must Pay Annual Fee.—The College of Physicians and Surgeons of the Province of Quebec recently brought suit against Dr. Auguste Bourbonnais, M.P. for Soulanges, for arrears for annual assessments to the College. The Court has recently given judgment for the plaintiffs, which means that the Quebec doctors must hereafter pay the annual two-dollar assessment levied by the College or cease the practise of their profession.

Toronto University Appointments.—On account of the resignation of Dr. R. R. Bensley and the increasing number of students taking lectures in the medical department, the following appointments have recently been made: Dr. W. H. Piersol, B.A., to be an instructor in biology and histology; Mr. C. M. Fraser, B.A., assistant in zoology; Mr. R. B. Thompson, B.A., class assistant in biology.

Queen's Medical Faculty, Kingston.—The students of the different departments of Queen's University have inaugurated a movement to raise $20,000 to $30,000 for the purpose of a new Convocation Hall; and at a meeting of the medical faculty the scheme received unanimous indorsement and a committee was appointed to raise a medical faculty fund. The medical faculty of Queen's has recently been at great expense in adding to the size and equipment of their building, so this recent action of the faculty will bear heavily upon them, but at the same time speaks well for their liberality.

Smallpox in Ontario.—The present epidemic of smallpox in the Province of Ontario is remarkable for its rapid spread and small death-rate. Since October 1st, there have been 580 cases, occurring in 63 municipalities, with three deaths. At the present time there are 433 cases and of this number the capital has 92 cases.

New Vaccination Order for Quebec.—The Provincial Board of Health of the Province of Quebec has ordered every Municipal Council to avail themselves of the provisions of the "Quebec Public Health Act" within five days, and adopt by-laws to the effect that within two days after such by-laws come into force every person in the Province must establish evidence of successful vaccination within the past seven years or unsuccessful vaccination within six months, and, failing this, unless vaccinated at once, they will be liable to a fine of five dollars with another dollar for each day of delay. Quebec has an extensive outbreak to cope with.

Field Hospital for South Africa.—The Imperial Government has accepted the offer of a field hospital from Canada for service in South Africa. Surgeon Lieut.-Colonel A. N. Worthington of Sherbrooke, Quebec, who has already seen service in the South African campaign, will be in command of the unit and associated with him will be Dr. H. D. Johnson of Charlottetown, P. E. I., as lieutenant, and Dr. Jones of Halifax, N. S., as captain. They will be accompanied by Dr. Roberts and H. E. Tremayne of Toronto.

New Dean at McGill.—The Board of Governors of McGill University have accepted the resignation of Dr. Robert Craik as Dean of the Medical Faculty and appointed Dr. Thomas G. Roddick, M.P., to succeed him. A resolution was adopted asking Dr. Craik to accept a seat on the governing board of the university. The new Dean is professor of surgery at the University.

GENERAL.

Bequest to Hospital.—The Massachusetts General Hospital through the will of Mrs. Susan C. Warren has been enriched by twenty thousand dollars. Other institutions were liberally remembered by Mrs. Warren.

A Royal Hospital.—The palace of Monzo, occupied by King Humbert of Italy at the time of his assassination, is to be converted into an asylum and hospital for children.

Doctors in Politics.—In France, 42 members of the Senate and 53 of the Chamber of Deputies are physicians, making a total of 95 physicians in the French Parliament.

A Christmas Donation.—Mr. William C. Whitney has sent a check for $6,000 to the Nassau County Hospital, located at Mineola, L. I., as a Christmas gift. He gave the hospital a like amount last Christmas.

The Use of Opium in Porto Rico.—Morphine is used extensively in the town of Juana Diaz, Porto Rico. It is estimated by the insular Board of Health that out of the 2,500 inhabitants 1,000 are victims of this terrible habit.

Medical Students in Switzerland.—The number of women students of medicine in Berne is 190; men students, 174. In Geneva 168 women and 183 men are pursuing medical studies.

Spread of the Plague.—The bubonic plague has reappeared in Honolulu and has been discovered in

Smyrna, Asiatic Turkey, while in Brazil and India its prevalence is unabated.

Faith Cure for Smallpox.—In Jersey City a family of ten was discovered less than a week ago in which eight members were suffering from smallpox. The father, although himself a victim, was treating his children by prayer alone. The eldest daughter died before she could be removed to the hospital and the others were found to be in a serious condition. In spite of their helplessness the family resisted the interference of the health officers.

French and Austrian Physicians.—Statistics show a notable decrease in the number of medical students and graduates both in Austria and France. In the former, in 1891, 721 diplomas were conferred by the universities of the Empire; in 1901, but 603. In 1891 there were 5,075 medical students registered; in 1901, 2,555; a diminution of 23 per cent. in the number of physicians; of the students, nearly 50 per cent. France shows a similar falling off. In Paris, in 1897, there were 5,000 medical students registered; in 1901, but 4,000.

Hypnotism for Degeneracy.—Judge Davis, President of the Board of Children's Guardians of Indiana, has given his consent to "Prof." Henry of a Chicago school of hypnotism to experiment with the children in the home maintained by the board. It is Mr. Henry's theory that by hypnotic suggestion he can start a train of thought in the minds of the children for better things. Children who have been taken from vicious parents will be experimented upon. Judge Davis says he does not believe it can do the children harm and possibly will have good results.

The Arabian Practitioner.—The Arabian physician's only claim to intellectual culture is the ability to read and write. He knows the toxic properties of certain plants and curative qualities of others, which he employs indifferently for all maladies. The remedies which he considers most efficient are bits of paper on which are written a verse from the Koran; these are to be swallowed by the patient. In other instances, the paper is carefully rolled and put in a pot to boil. The water is drunk by the patient as hot as can be borne.

Anthropometrical Laboratory.—An anthropometrical laboratory will be offered to the university over which Prof. Paolo Mantegazza presides, upon the occasion of his jubilee. The new laboratory will be open to students and investigators of anthropometry, and will serve for the collection of data concerning variations in the principal characteristics of the human race, morphological and physiological, according to race, sex, age, social position, etc.

Dinner to Dr. Hart.—On December 19th the physicians of Colorado Springs tendered a dinner to Dr. James A. Hart, the occasion being his retirement from active practice. Over thirty medical men gathered at the new Antlers Hotel to evidence the high regard in which Dr. Hart is held by his fellow-townsmen. Dr. S. E. Solly was the genial and witty toastmaster, and toasts were responded to by Dr. Charles A. Powers of Denver, Dr. C. F. Gardiner of Colorado Springs, Dr. C. E. Edson of Denver, and Drs. Gildea, Swan, Campbell and Hutchings of Colorado Springs. Dr. Hart graduated from the College of Physicians and Surgeons of New York in 1874, and after a term in the New York hospitals settled in Colorado Springs where for a quarter of a century he has been one of the leading practitioners.

Hot Bread.—Mrs. Helen W. Atwater has written for the Agricultural Department a bulletin in which she argues that it is not the fact of its being hot which makes hot bread injurious. Hot bread may be injurious just as cold bread may be and the cause is identical in both cases. The advantage on the score of economy only, to say nothing of superiority in actual qualities of nutrition of home-made bread that is the work of a housewife who knows her business, is also presented. Experiments made in different localities show that the average price of baker's bread is more than 100 per cent. above the cost of the raw materials from which it is made.

The Marine-Hospital Service.—A bill has been introduced into Congress by Representative Hepburn to increase the efficiency of the Marine-Hospital Service. Providing for the change of name, it transfers all officers and employees of the old to the new service, with the same rank and pay, except as to the Surgeon-General; this officer is to receive the pay of the Surgeon-General of the army. Commissioned medical officers of the service in charge of administrative divisions in Washington are to rank as Assistant Surgeons-Generals; the relative rank of the other officers of the service is fixed with, but after that of army and naval surgeons. A board is authorized, composed of the Surgeon-General of the army and the navy, the Chief of the Bureau of Animal Industry in the Agricultural Department, and the Director of the Laboratory in that bureau, and five other members not regularly in Government employ, to consult with the Surgeon-General of the "Health Service" on the work of the Hygienic Laboratory; and provision is made for conferences between the Surgeon-General of the "Health Service" and delegates from the various States and Territories on matters relating to the interests of the public health. Uniformity in the registration of vital statistics is aimed at by the bill, which makes it the duty of the Surgeon-General of the newly-named service to prepare proper forms for collecting such figures in conjunction with the State Boards of Health, and to compile and publish them as a part of the reports of the service. The Secretary of the Treasury is to prepare rules for the service, as well as uniforms for its officers and employees, and is to make a yearly report to Congress of the work performed.

Obituary.—Dr. Amos C. Lewis died December 29th at his home at Sedgewick Avenue and Hampden Place in The Bronx. He had been ill five weeks. He was well known as a specialist on skin diseases and was the visiting physician at Fordham Hospital.

Dr. James Burton Snover, one of Pennsylvania University's best-known oarsmen, died December 28th at the University of Pennsylvania Hospital of typhoid fever. He was captain of the 1900 championship crew. He was twenty-five years old.

Dr. John Bell, the highest ranking Knight of Pythias in the world, and one of the best-known physicians in Southwestern Michigan, died yesterday at Benton Harbor, Mich. He was a prominent member of the Masonic fraternity throughout the State, and was elected Major General of the uniform rank, Knights of Pythias, of the World, in 1898. He was once mayor of the City of Benton Harbor, and had been identified with the growth of the city for forty years.

Dr. James M. Wallis died in Philadelphia December 28th in the seventy-seventh year of his age. Born and educated in Philadelphia, Dr. Wallis practised there, was prominent in the medical service during the Civil War, and again resumed practise in that city. He retired from active practise twenty years ago.

Royal honors will be paid to the body of Dr. Allanro Read, the American dentist, who had resided in Copen-

hagen since 1860, and who died December 30th. Dr. Read was a native of Pennsylvania, and occupied much the same position there as did the late Dr. Thomas W. Evans of Philadelphia in Paris. He was patronized by the royal family of Denmark, the royal family of Sweden, the Dowager Empress of Russia, and Queen Alexandra, and enjoyed the friendship of members of various royal families, diplomats, and other notabilities. He declined to accept a title and other honors and retained his American citizenship. Wreaths from the Danish royal family will be deposited on Dr. Read's coffin on the day of the funeral.

A physician believed to have been the oldest member of the medical profession in England recently died at Monkeaton, Northumberland, in the person of Dr. John Warren Edgar. He was born in September, 1803, and had therefore lived to the remarkable age of ninety-eight years, most of which were spent in practice in Kirkby Stephen, Westmoreland. He took his degree in 1828, and continued in practice until a few years ago.

Dr. James Snyder MacKie, littérateur, linguist, financier and physician, died December 30th at his home in Newark, N. J. He had been ill only two days when he was stricken with apoplexy. Dr. MacKie was seventy-seven years old. He was born in Cincinnati, but had lived in Newark most of the time since 1864. He was prominently identified with State Department matters during the administration of President Lincoln. He served with distinction in the civil war, and was a member of the Loyal Legion.

TRIGEMINAL NEURALGIA—DERMATITIS GANGRENOSA—NORMAL SOLUTION OF SALT IN LONG OPERATIONS—TERTIARY SYPHILITIC LARYNGEAL STENOSIS—ACUTE MILIARY TUBERCULOSIS IN CHILDREN—TUBERCULOUS MENINGITIS—CONGENITAL DILATATION OF THE SIGMOID COLON.

Late in November and during December the following British society proceedings are reported, and in them the best of the papers are the following:

T. H. Morse, at the Clinical Society of London, November 22, 1901, reported two cases of intracranial section of the second and third divisions of the trigeminal nerve for severe neuralgia. In both patients the Hartley-Krause operation was performed. The bone was removed with mallet and chisel and with gouge-cutting forceps. After section of the second and third divisions of the fifth nerve, the foramina ovale and rotundum were blocked with Horsley's wax, for the purpose of preventing reunion of the divided nerves. In both cases cure was obtained. The first was done more than two years ago.

J. Hutchinson, Jr., exhibited four cases in which he had done the same operation. The last was one six weeks old, and was a complete cure. In another case operated on four years ago, the patient had been subjected to several other operations, including division of nerves and lastly removal of Meckel's ganglion. The other three cases had also suffered for many years. In this individual the Gasserian ganglion was removed by Krause's method with success. The last case suffered neuralgia also in the occipital region. Here Krause's operation was done, the ganglion being removed with the lower two branches of the fifth nerve, just behind the ganglion. The occipital neuralgia disappeared, showing that it was a reflected one. In none of these cases had there been any return of the pain. He preferred the temporal operation in preference to all others through the pterygoid region. The advantages of removing only the lower portion of the ganglion were that the cavernous sinus is not interfered with, there is no danger of injuring the oculo-motor nerves, there was no need to tie the meningeal artery, and there was no post-operative anesthesia of the cornea. On this last point the author stated that strict antisepsis and sewing up the eye-lids immediately after the operation prevented it. He quoted a case in which by accident the ophthalmic branch of the fifth nerve had been divided, which was followed by corneal anesthesia and later by ulceration, and finally by destruction and removal of the eye. The last advantage of the temporal operation is that neuralgia, as a rule, does not occur in the ophthalmic branch of the fifth nerve, and hence this route aids in avoiding it. A large flap is not necessary. In one case he tied the external carotid artery for hemorrhage. The position of sitting erect in a chair is the best, although the anesthetists might say to the contrary. A curette will enable one to remove part of the ganglion, but not cleanly. The mortality in Great Britain for this operation is not over 10 per cent. His own record is five without a death. Doyen's method of operating, which entails an unnecessarily extensive operation, he condemned. The major operation should not be postponed too long, and should always be done whenever the superior maxillary branch of the nerve is involved.

Dr. Finny, at the Royal Academy of Medicine in Ireland, November 15, 1901, read notes of a case of dermatitis gangrenosa, which occurred in a child two years and nine months old. It died five days after admission to the hospital. Its condition when brought to the institution was extreme prostration, with circular, punched out sores varying in size from one-half to two inches in diameter more or less, covered with a yellow, green, pultaceous scab, and distributed widely over his back, thighs, genitals, hands, face, scalp, ears, forehead, and eyelids. After poulticing with boracic acid, the ulcers were clean, smooth and sharply defined at the edge, and of a deep, raw meat color. No bullæ were visible anywhere, nor any sign of varicella. Vaccination had been performed two and again half a year before. There was no history of syphilis nor of exposure to any contagion. There had been no chickenpox in Dublin or Ireland except remote from that city. At the autopsy, examination revealed caseating tuberculosis of the thymus gland, lungs, bronchial and mesenteric glands. Before admission the child had been under the care of a competent physician, who noted that the disease was a case of impetigo, which was rapidly going on to gangrene. The eyes were in a state of panophthalmitis. It seemed to be a well-marked example of what Stokes in 1807 described as "eating hives," "white blisters" and "pemphigus gangrenosus." Later Hutchinson in 1879 calls, what appears to be the same disease, "varicella or varaccinia gangrenosa." Dr. Finny, however, preferred the comprehensive title of dermatitis gangrenosa, which Croker had given it. The cause of the disease he considered some special microbic infection attacking children suffering from some pustular disease.

Dr. Macnaughton-Jones, at the British Gynecological Society, November 14, 1901, read a paper on the use of artificial serum in prolonged operations. His illustrative case was a woman, forty years old, curetted and relieved of a polypus some time before the operation. She had had pelvic pain for over seventeen years, since the birth of her last child. Before the operation she suffered from intense pain, frequent fainting and threatened collapse. At the operation the inlet of the pelvis was found to be completely closed by a smooth, firm, plastic bed, which completely hid

the adnexa. On breaking this down, the latter were found to be converted into thickened adherent and enlarged tubes with old pus sacs and the ovaries into enlarged cystic masses, with purulent infiltrations Removal of all was extremely difficult. One of the pus sacs ruptured and a large drain was left in and removed on the fourth day. Recovery was uneventful. The case, with another which he had recently shown the society, well illustrated the danger of temporizing with such extreme disease of the adnexa. Such a hesitating policy finally necessitated the performance of an operation far more difficult and prolonged than any ordinary hysterectomy. In this particular case if it had not been for the free use of normal salt solution the patient would have died. The work, even with rapid operating, lasted nearly two hours.

W. G. SPENCER, at the Laryngological Society of London, November 1, 1901, showed a patient suffering from tertiary syphilitic laryngeal stenosis. This was treated by laryngo-fissure without a tracheotomy. The result of it all was a most satisfactory cure. There was no dyspnea and the patient had an audible voice.

S. STEVENSON, at the Society for the Study of Diseases in Children, November 15, 1901, exhibited a child seventeen months of age suffering from acute miliary tuberculosis, with both pulmonary and cerebral manifestations. Double optic pupillitis existed and a typical tubercle was present in the choroid coat of the right eye. There was also in addition a tuberculous ulcer involving the conjunctiva of one lid. Scrapings from this ulcer were rich in tubercle bacilli. The free edge of one eyelid had also been destroyed.

E. CAUTLEY read a paper on the etiology and pathology of tuberculous meningitis in children, based upon the best postmortem and clinical findings in the last twenty-seven fatal cases under his care. Twenty-two were children under five years of age and only five were between that age and ten years. Family predisposition existed in five cases. In only two was the disease limited to the membranes of the brain and spinal cord. In twenty-three the glands of the mediastinum were cheesy and in four the mesenteric glands were also cheesy. His views were summed up briefly as follows: So-called heredity means exposure to infection. Injury is rarely an exciting or a predisposing cause. The respiratory tract is the great channel of infection. The alimentary tract is rarely primarily affected. Tuberculous milk is rarely if ever the source of infection. The outlook for life is always hopeless on account of the extent of the tuberculous disease elsewhere in the body. The evidence obtained from the examination of the brain after death shows that all operative treatment should be discarded as dangerous.

C. N. GWYNNE, at the Sheffield Medico-Chirurgical Society, November 7, 1901, showed a case of congenital dilatation of the sigmoid colon. The boy was sixteen years old, obstinately constipated since birth, with later in life, chronic enlargement of the abdomen, up to thirty-one inches in circumference at the navel before admission. No action of the bowels could be obtained, and an iliac colotomy was commenced. After the operation the boy improved in general health and his abdomen reduced to almost normal proportions.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Stated Meeting, Held November 23, 1901.

The President, Howard Lilienthal, M.D., in the Chair.

Needless Laparotomy.—Dr. John C. Munro of Boston read the paper of the evening, in which he said that it is an important thing for medical men occasionally to pass their sins through a clearing house, in order properly to strike a balance of advance in medicine and progress in diagnosis. As for himself he was ready to confess to certain needless abdominal sections, needless in a sense that at the operation no properly surgical lesion was discovered, although beforehand the diagnosis of some grave surgical lesion was made. In his cases there are no abdominal sections for pneumonia presenting abdominal symptoms, although on more than one occasion such patients have been sent to him for operation by medical men, and no laparotomies in cases in which appendicitis and typhoid fever were confounded because of the similarity of symptoms. Dr. Munro detailed some eight instructive cases.

Acute Phosphorus-Poisoning.—The first case was of a delirious patient who was brought in the hospital ambulance. The only history obtainable was that she had taken some oil to produce abortion. The condition present seemed to be sepsis in the abdomen. There was pain and tenderness with distention of the abdomen, a condition of jaundice and, according to the report, there had been no stools for several days. On opening the abdomen the usual acute fatty degeneration of all the organs was found.

Hypertrophic Cirrhosis.—The patient was a man of thirty-two years admitted to the hospital in a very weak condition. He had seven or eight loose stools daily for a week and suffered from considerable loss of weight. While there was some jaundice the stools were alternately light and dark, the change taking place seemingly without any good reason. The edge of the liver was found to be as low as the navel and the presence of some biliary condition was suspected. At operation a regular, smooth enlargement of the liver was found, evidently due to hypertrophic cirrhosis. The patient recovered from the operation without incident, his jaundice became markedly less and his general condition improved.

Acute Nephritis.—The patient was a widow who was referred to Dr. Munro for operation for appendicitis. At first she had complained of pain on the left side which afterward shifted to the right side. It seemed to be localized in the lower part of the region of the kidney and there was marked tenderness on this right side. The general condition was very bad and some acute inflammatory process was thought to exist. In the urine pus, albumin and casts were found, but the condition was considered not to be primarily nephritic. At operation nothing was found to account for the symptoms and the conclusion was that they were due to the acute nephritis. The patient's general condition seemed to improve somewhat immediately following the operation, but after some time her disease progressed and she died three weeks after operation.

Nephritis Simulating Appendicitis—In a fourth case the patient had suffered for several years with a tendency to more or less colicky pains in the abdomen. There had been several distinct recurrences of acute exacerbations of some intra-abdominal condition that caused severe pain. Slight edema of the lids had been noticed, but no edema anywhere else in the body. There was localization of the pain in the right iliac region. Marked leucocytosis was present during the last attack and there was general abdominal tenderness with fulness over the right kidney. The patient was evidently losing ground and required prompt treatment if her condition were considered to be of a surgical nature. Under ether narcosis an incision was made on the right side of the abdomen, but absolutely no pathological condition was found in the liver or in the biliary tract and no signs of any inflammatory condition in the neighborhood of the appendix. Convalescence after the operation was very satisfactory. The general

symptoms improved and three weeks later the patient was better than she had been in several years.. After the operation the only diagnosis that seemed possible was simple acute nephritis with marked tendencies to relapse. This would account for the localization of the symptoms. Though they are unusual, such painful conditions are sometimes met with in simple nephritis.

Delirium Tremens.—The patient shortly before his admittance to the hospital had been on a drinking bout. A chronic renal condition was known to be present and the urine showed signs of it. On admittance to the hospital the principal symptoms in the case were of an acute abdominal nature. There was some suspicion of a pancreatic surgical condition, and as the symptoms were very severe and seemed to demand immediate interference, the abdomen was opened but no pathological condition discovered. There was a hardening of the pancreas that seemed suspicious and a specimen was removed for examination, but it proved negative.

Morphine Habit.—The patient, a woman of questionable character, while under the influence of liquor, fell into the hold of a vessel in the harbor. The symptoms presented were those of some acute abdominal condition and, as the fall had been a serious one, the suspicion was aroused that a rupture of the kidney might have taken place. The abdomen was opened but absolutely nothing traumatic was found. After the operation, it was discovered that the patient, besides being alcoholic, had the morphine habit. By withdrawing the drug almost any train of symptoms could be induced. The patient recovered without incident.

Obesity.—The patient was a man who previously had lost considerable in weight and then began to gain very markedly in size and in avoirdupois. Just before his increase in weight occurred, an indefinite tumor in the right kidney region had been noticed, which was tender to palpation and caused considerable discomfort on movement. Jarring motions particularly were felt severely in the right side. Once obesity set in a steady increase in size occurred, the circumference of the abdomn increasing an inch per day. It was concluded that some kidney trouble must be present and that the remarkable increase of the abdomen was due to ascites. At the operation nothing was found except an immense amount of fat in the omentum. This was of a very soft character, lacking even the usual consistence of abdominal fat. It gave a modified wave when the abdomen was tapped with the fingers. After the operation the patient's subjective symptoms were relieved for a time. The tendency to increase in weight also ceased for some time, though it recurred afterward, and Dr. Munro learned that obesity was a prominent characteristic of the family history. A brother and sister of the patient each weighed over 450 pounds.

Supposed Pancreatitis.—The patient was a woman who had been dragged over the dashboard of a wagon and kicked by a horse which was running away as a result of a defect in the road over which she was driving. At the time of the accident she vomited some blood. Nearly a year after the accident she began to vomit daily, though usually the vomit was composed of bitter material, seldom food, and never blood. This vomiting took place usually in the afternoon, but did not occur at night. There was no jaundice, but the patient's appetite was capricious and she had lost thirty pounds in weight; the stomach was not dilated. As she had already recovered damages from the town in which the accident had occurred, the traumatic neurosis symptoms, usually so persistent until damages are awarded, could be practically excluded. In the epigastrium there was tenderness and marked rigidity. Only very slight rigidity remained, however, under ether narcosis. An exploratory laparotomy was advised. It was thought that a tumor could be felt in the epigastrium and the most probable diagnosis seemed to be a traumatic pancreatitis with subsequent inflammatory changes. After the abdominal incision was made it was found that the supposed tumor was due to an absolutely normal pancreas lying over a rheumatic spinal column which was very prominently arched forward. The symptoms in the case were evidently hysterical manifestations. Recovery from the operation was rapid and complete. The laparotomy was not a useless one as far as its therapeutic effect was concerned. The patient's symptoms were relieved at once and have not recurred since. The vomiting has ceased, her appetite has improved, she has regained the weight lost and her general condition is such that she considers herself cured.

Hypertrophic Hepatic Cirrhosis.—In opening the discussion Dr. Potter said that he had seen one case of hypertrophic cirrhosis operated upon under the false impression that the symptoms produced were due to some intra-abdominal inflammatory condition. The fever that occurs during the course of hypertrophic cirrhosis is very apt to lead to the commission of such a mistake. Hypertrophic cirrhosis is, however, much rarer in women than in men. Dr. Munro's case is therefore all the more interesting for this reason. The diagnostic error is comparatively easy to make and now that it is more than formerly the custom to operate on biliary conditions it is probable that a number of useless operations will be performed on patients suffering from this condition.

Syphilitic Liver.—Dr. Brewer said that he had seen needless laparotomies in certain of the classes of cases mentioned by Dr. Munro and had himself twice operated on patients who proved to be suffering with syphilis of the liver. The symptoms produced by hepatic syphilis in the tertiary stage may be absolutely identical with those produced by surgical diseases of the gall-bladder. There may be biliary duct occlusion, with pain and subsequent jaundice. In one of the cases all the symptoms were perfectly pathognomonic of gallstones. The condition proved to be a large gumma of the liver. This had broken down, however, and drainage was absolutely needed so that the operation could not be pronounced useless.

Needless Operations for Gastric Conditions.—In two patients referred to Dr. Brewer the symptoms seemed to be surely those of cancer of the stomach. One of them proved later to be atrophic gastritis. The other operated upon proved absolutely negative as far as any surgical condition of the stomach could be found and to this day it is not quite clear what was the cause of the severe stomach symptoms. Operations for gastric cancer in which the opening of the abdomen has given absolutely negative results are not infrequent.

Obesity and Ovarian Cysts.—In one patient an enormous tumor developed that seemed to rise out of the pelvis. By palpation fluctuation could apparently be obtained. The diagnosis was an immense ovarian cyst. On operation, however, it was found that there was enormous distention of the abdomen by a fatty growth in the omentum. It was impossible to raise the omentum and it had to be cut through. Altogether the distance was eighteen inches. The fat lacked the consistency of normal fat. Beneath this huge omentum no pathological condition of the abdominal or pelvic organs could be found.

Pneumonia and General Sepsis.—Some years ago Dr. Brewer saw a patient who had suffered from pneumonia in which the crisis had come on the sixth day. The temperature had been normal for nearly a week, when acute abdominal pains developed with a tempera-

ture of 102° F. and a pulse of 100. There was a history of four or five previous attacks and there was localized tenderness in the region of the appendix. The next day the abdomen was rigid and the pulse and temperature had both risen. It seemed certain that the patient was suffering from appendicitis and two consultants who were called agreed with this diagnosis. The patient was considerably run down as the result of the pneumonia, however, and the fulminant character of the apparent appendicitis had still further sapped his strength so that operation seemed hopeless. There was great distention of the abdomen and there seemed to have been a perforation in the appendix. After death it was found that there was no intra-abdominal lesion. The patient's condition was due entirely to a pneumococcus septicemia with tympanites from distention of the intestine because of peristaltic paralysis. Dr. Brewer has seen three or four of these cases in which general sepsis simulated very closely intra-abdominal conditions.

Pernicious Anemia.—Dr. William B. Coley said that he had seen one case operated upon in which all the classic symptoms of cancer of the stomach seemed to be present. The patient had lost some forty pounds in weight and seemed to be utterly unable to retain anything on his stomach. The symptoms of gastric carcinoma seemed so clear that no blood-examination was made. After laparotomy no pathological condition of the stomach could be found. The case proved to be one of pernicious anemia.

Multiple Hepatic Abscess.—Dr. Fiske reported a case in which the history was that of a servant admitted to the hospital with a temperature of 104° F. and a rapid pulse. She had slipped and fallen across a railing. She was pregnant at the time and an abortion resulted. There was no tenderness over the abdomen, but the uterus was cleaned out on general principles, and this was followed by a drop in the temperature that seemed to confirm the suspicion of intra-uterine sapremia. The second day afterward, however, her temperature went up again and nothing could be found to account for her condition. She continued to suffer for several days and then died. At the autopsy a number of abscesses of the liver were found. One of these was of the size of a hen's egg, a number of them were as large as marbles, while some were only minute points of pus. None of the symptoms during the course of the case pointed to any involvement of the liver. There was no tenderness of the abdomen at any time.

Gastric Crisis.—Dr. Morris Manges reported some cases in which he had seen or knew of operations being performed for supposed abdominal conditions when the real etiological factor in the case was tabes and when the symptoms were gastric or intestinal crises of the disease. Two liver cases that he has seen operated on proved to be due to syphilitic cirrhosis. One of them simulated cholelithiasis very closely. Atrophic cirrhosis of the liver sometimes simulates very closely cancer of the liver, especially when the nodules of the surface of the liver are large.

Hypertrophic Cirrhosis.—Dr. Manges has seen two cases of hypertrophic cirrhosis operated on with the idea that a surgical condition existed. In one case the diagnosis was cholelithiasis. In the other it was considered that a neoplasm was present and there was suspicion that it might be an operable carcinoma of the pylorus. It is important to differentiate cirrhosis of the hypertrophic variety from other affections in the epigastric and right hypochondriac regions. Thus far insufficient attention has been paid to this serious problem. While it is usually insisted by surgeons that exploratory laparotomy involves very little risk, Dr. Manges has come to consider this kind of operation as the most serious for his patient. When the laparotomy is undertaken without assurance of the condition that is to be found the patient is always in grave danger.

Hysteria and Abdominal Conditions.—Dr. Henry C. Coe said that if gynecologists were as frank as their surgical brethren there would be more needless laparotomies to confess to. Hysteria particularly is apt to induce sets of symptoms that simulate very closely abdominal conditions for which not a few abdominal operations have been done. Ectopic gestation often gives very dubious symptoms yet there is no doubt of the advisability of operation on even very slight grounds. Gumma of the liver simulates pyloric carcinoma very completely at times. Twice in Dr. Coe's experience a lipoma of the omentum has been diagnosed as cyst of the ovary. The surgeon's only protection against hysterical simulation of abdominal surgical conditions is to keep the patient under observation for a considerable period.

Apparent Echinococcus.—Dr. Foote reported a case in which the patient had been operated upon for echinococcus of the liver. Two years later failing health again called attention to the condition. The liver was found enlarged, but there was no ascites. There was a slight febrile temperature. It was concluded that the echinococcus cysts were recurring. On operation some hypertrophic cirrhosis of the liver was found but absolutely no echinococcus. A needle was passed into the liver in various directions, but no pus came. The patient was very much improved by the operation and gained in health and strength with a relief of symptoms.

In closing the discussion, Dr. Munro said that in one of his cases of operation for gumma of the liver he had found the gummatous tissue in a necrotic condition and had instituted drainage. This, of course, is not an operation to be regretted. Dr. Munro finds he must be most careful of cases of pneumonia which give abdominal symptoms. In all patients pneumonia must be ruled out. Dr. Munro has found the X-rays very useful for this purpose. In cases of appendicitis nephritis must be excluded. He considers multiple abscess of the liver much more common than has been thought.

Danger of Uterine Tamponade.—Dr. Coe detailed his recent experience with a case that pointed out to him a hitherto almost unsuspected danger from tamponing the lower segment of the uterus to induce labor. The patient was a woman in wretched health, a multipara, for whom it seemed desirable to bring on premature labor. She was given a few whiffs of chloroform and about two yards of gauze were packed into the lower segment of the uterus. At the time of the tamponade it was noted that the placental bruit was loud. It was concluded that there was a low implantation of the placenta. A couple of hours later there was a sudden gush of blood. Most of the gauze was removed and the hemorrhage ceased somewhat; though the patient did not suffer from ordinary labor pains, there were contractions and cramp-like pains that were more distressing. The fetal heart sounds were distinct. After a time the hemorrhage recommenced and continued so that there was an anticipation of premature separation of the placenta. Dr. Coe summoned assistance and made a rapid delivery with the high forceps. There was considerable bleeding, at least twenty ounces of blood being lost. It was found that the placenta had been detached over one-half its area and that this was undoubtedly the cause of the bleeding. After the delivery examination of the uterus showed the presence of a sessile intra-uterine fibroid. The course of the case since delivery has been normal. The child is perfectly well. It seems certain that the insertion of the gauze into the uterus was the occasion

for the detachment of the placenta. Either the placenta was directly pushed away from the uterine wall by the gauze, or at least so much pressure was made upon its lower edge that the first contraction of the uterus caused its detachment. If delivery had been delayed in this case there seems no doubt that both lives would have been lost. The insertion of the gauze is usually considered the simplest and safest method of inducing labor. This case shows one of its dangers and indicates the necessity for determining if possible whether there is a low implantation of the placenta at the time of tamponing.

Practical Questions.—In answer to a question Dr. Coe said that he knows no way of guarding against this accident with any assurance. It must be remembered that detachment of the placenta without dilatation of the cervix is a rather fatal complication. The first sign of the occurrence of such a complication must be the signal for interference. If, in such a case, the use of high forceps proves impossible, then the indication would be to open the abdomen, especially if the patient were in a hospital. In private practice, of course, Cæsarian section is almost impossible without great preparation.

Intra-Abdominal Hemorrhage.—Dr. Brewer gave the details of an accident treated in his service at Roosevelt Hospital. The patient was an Italian and was thrown down by a wagon, though it is not known whether he was run over. When he came into the hospital he had a black eye and there was some subconjunctival hemorrhage. He gave evidence of great shock, due seemingly to his head injury. Twelve hours later the patient had an extremely weak pulse, was pale and anxious looking, and had distinct abdominal rigidity and tenderness over all the abdominal surface, though there were no bruises of the abdominal wall. Both flanks were very flat, the whole picture being that of a large intra-abdominal hemorrhage. His abdomen was opened and a large rupture of the spleen was found, almost completely separating that organ into two parts. The patient was in such a low state that nothing could be done except to pack the slit in the spleen by means of gauze which was conducted out of the abdomen through an incision in the posterior wall made for purposes of drainage. The patient was infused with 3,000 c.c. of salt solution and, after complete evisceration, the abdomen was thoroughly wiped dry. The patient began to improve at once; he looked brighter, there was no temperature and his heart improved very much. On the fourth day there was an unexpected rise of temperature to 102° F.; on the fifth day it was half a degree higher and the pulse was 110. On the sixth day the temperature rose still higher. There was no rigidity, no distention of the abdomen, no tenderness, but on the seventh day the pulse was 160 and the temperature nearly 106° F. There were lung complications, no head symptoms, no leucocytosis and the case seemed a mystery.

Suggestions as to Etiology.—Dr. Foote said that the case would probably prove to be one of some form of intestinal septicemia. At autopsy injection of the intestines would be found, if not adhesions. There would be an intense peritoneal sepsis, though without the usual acute symptoms. Dr. Coley said that in such cases, especially after gunshot wounds, some form of abdominal sepsis was usually found. The local symptoms were very slight and commonly only a little bloody fluid was found in the abdominal cavity. The septic condition of the abdomen, however, was sufficient to cause the severe systemic symptoms, though without the localizing symptoms. Dr. Fiske said that in such a case he would be apt to suspect the existence of a subphrenic abscess. The absence of leucocytosis does not of itself negative the possible existence of a serious septic or purulent condition. There was no leucocytosis in President McKinley's case and yet a serious pathological condition had developed.

Dr. Howard Lilienthal said that the subconjunctival ecchymosis suggested the possibility of head injury. While the special senses seem not to be affected, a study of the eye-ground might have given some information as to cerebral injury. In some of these obscure cases undoubtedly the serious lesion was intra-cranial.

Symptomless Septic Conditions.—In closing the discussion Dr. Brewer said that undoubtedly the condition seemed to him to point to abdominal sepsis. Against this conclusion, however, were the following facts: The gauze packing when removed from the abdomen was very properly sweet; there was never any induration to be found on palpation; there was absolutely no rigidity of the abdominal muscles; it was very noticeable on examination, even with the temperature at 106° F., that the abdomen was hollow and was not distended to the slightest degree. By exclusion of other complications, however, one can think only of peritoneal sepsis. With regard to the question of head injury there was no discharge of blood from the ear, nose, or mouth, so that there was nothing to point to the possibility of fracture of the base with subsequent infection of the meninges through these channels.

CLINICAL SOCIETY OF THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

Stated Meeting, Held November 4, 1901.

J. A. Bodine, M.D., in the Chair.

Infantile Acromegaly.—Dr. Charles G. Kerley presented three patients. The first, a case of infant acromegaly, nine months old, presented marked hypertrophic growth of the right leg. At birth the first and second toes of the right foot were considerably enlarged, and the foot was from one-fourth to one-half inch longer than the other. The hypertrophic growth of the bone as well as of the soft parts has increased steadily since birth. The right leg is one inch longer than the left. The hands also appear to be larger than might be considered proportionate. Very few such cases have been described. Klebs has described them as cases of infant acromgaly. Furnival has reported 34 cases of adult acromegaly which came to autopsy, and in all those they found either hyperplasia or cystic degeneration of the pituitary gland.

Congenital Heart Lesion.—The second patient, a girl nine months old, presented this condition. She suffers no discomfort whatever. The only sign of the lesion is the loud and blowing murmur with its great area of diffusion, it being very loud over the entire thorax front and back.

The third case presented the clinical picture of a congenital heart lesion which represents fairly well the condition usually present in older children. There is cyanosis indicated by the blue lips and the congested appearance of the face. There is marked clubbing of the fingers and toes. Upon slight exertion the child becomes indigo blue. She has occasional attacks of severe pain in the cardiac region, followed by a short period of unconsciousness. The murmur is loudest over the base; it can be heard distinctly all over the anterior portion of the chest and faintly behind. There is hypertrophy of the right heart, the line of absolute dulness extending to the right mammary line.

The chief points of interest in connection with congenital cardiac affections in children rest in the differential diagnosis from the acquired forms of heart disease. Children under two years of age very rarely

have acquired heart lesions, for the reason that rheumatism at this period of life is extremely rare. The age, therefore, is of some assistance in differentiation. The nature of the murmur is significant. It is loud, harsh in character, with a wide area of diffusion. This with the cyanosis, clubbing of the fingers, etc., renders the diagnosis fairly easy. Anemic murmurs sometimes have to be considered in this connection. The anemic murmur is soft, rather musical in character and heard over a comparatively small area, accompanied by a venous hum in the vessels of the neck. Autopsies show the most frequent congenital lesions to be stenosis of the pulmonary artery, with an open foramen ovale or an opening into the intraventricular septum.

Dr. Baron asked how long the heart might continue to compensate itself and the child not show other characteristic signs of a child with congenital heart lesion.

Dr. Kerley replied that this would be a hard question to answer in the absence of positive knowledge as to the nature of the lesion. In the older child the cyanosis indicates without any doubt an opening either in the intraventricular septum or a patent foramen ovale.

Dr. Katzenbach had seen cases in which there was fenestration of the valve, but no other symptoms.

Dr. Wyeth said the first case Dr. Kerley presented—that of acromegaly or hypertrophy of the right lower extremity—suggested some surgical consideration, in order to protect the child in its further development from deformities of the spine due to one extremity being shorter than the other, and suggested that in such cases the shorter side be elevated so that when the child walks it will develop the left side as well as the right. The growth of the bones will come when the child is fully developed. When that condition of hypertrophy shall have ceased it will be perfectly justifiable to cut that leg down by resection of the bone of the femur to the levl of the opposite side, and subsequently the femur and tibia, bringing the extremities to about the same length.

Dr. Townsend had operated on similar cases. It is more common to find the hypertrophy in the lower than in the upper extremity; in fact he could only recall one case where the disease was located in the upper extremity. Four or five years ago he operated on a young woman who had enlargement of two toes. The second toe was four inches longer than the great toe. Removal of the enlarged toes left the foot in good shape and enabled the patient to wear two shoes of the same size, whereas, prior to operation she had worn one shoe five or six sizes larger than the other in order to accommodate the hypertrophied toe. Dr. Townsend thought there would be a difference of opinion as to the advisability of surgical interference as suggested by Dr. Wyeth. If the child grows well and healthy, it is probable that the disease may be self-limiting or, in a measure, self curative, and therefore it would be questionable to do an excision.

Ossifying Periostitis.—Dr. Townsend read a paper on this subject and presented a patient from whom he had removed a bony tumor, 9x4x2 cm., from the front of the thigh, just above the knee, which, on examination, proved to be an exostosis. It was due to a blow received two months prior to the operation. Before its removal the patient was unable to flex his knee more than 30°, owing to the restriction due to the bony mass in the lower end of the quadriceps extensor femoris. Recovery was uneventful and the result perfect. He can use his knee as well as before he was hurt. The report of this case will appear in full in the MEDICAL NEWS.

Myofibroma of the Fallopian Tube.—Dr. J. Riddle Goffe discussed this subject and presented a specimen. He said that fibroids may arise in all tissue that has fibrous or muscular elements, but their appearance in the uterus is more familiar, although they are found in all parts of the body. Their origin, of course, is still obscure. If they originated in the muscles of the blood-vessels there is no reason why we should not have fibroid tumors in every part of the body where blood-vessels retain their muscular coats. This is the first case he had seen of a fibroid tumor of the Fallopian tube. The literature on this subject shows that Jacobs of Brussels reported a case in 1898. Dr. A. Palmer Dudley has seen one case since Jacobs' report These are the only cases that Dr. Goffe has found. The growth in this case is situated three-quarters of an inch from the horn of the uterus in the tube on left side; it has no connection with the uterus; it perfectly surrounds the lumen of the tube, so that a fine straw passed through the Fallopian tube passed completely through the diameter of the tumor. It is about three-quarters of an inch in diameter, and has been badly cut to pieces by the pathologist. He was very anxious to make sure that there was no mistake about his diagnosis and took sections in all directions. The history of the case is as follows: The patient, a young woman, nineteen years of age, had been a chronic invalid for four years, had not been out of the house for three years, and was incapacitated from pain and dysmenorrhea. Finally, she became disturbed mentally. She developed very marked mental symptoms and was on the high road to the insane asylum when she came under treatment last March. She had a retroflexed uterus with an enlarged ovary and a fibroid tumor near the horn of the uterus. The mental condition, he believed, could be relieved by change of scene, and he told her positively that she could be cured and thus made a marked impression on her mind. Her home was 500 miles away and her parents were loth to have her come to New York for treatment, but finally consented, and an operation for the relief of the retroflexed uterus was performed. The operation was done through the anterior fornix of the vagina; and on delivering the uterus into the vagina the disease of the left tube was found. The patient finally recovered.

Dr. Jeffries stated that this was the first case he had seen since his connection with the Polyclinic laboratory, extending over a period of from twelve to fourteen years, or with the laboratory of Bellevue Medical College.

Deciduoma Malignum.—Dr. Ladinski reported this case. H. G., born in Austria, aged nineteen years; family history negative; previous history good. Married one and a half years; has had one child, ten months ago, which she nursed for eight months. Menstruated in April and May; no menstruation in June. About the middle of July she began to have pains in the lower part of the abdomen; was examined in the dispensary, where she was told that she was pregnant. About the end of July she had some uterine hemorrhage and later about a quart of clear fluid tinged with blood escaped. Felt well until about a week later, when she was again seized with uterine hemorrhage at night and was tamponed by a physician. Dr. Louis Friedman was called in the morning, when he found her bleeding severely; he removed a large clot of blood from the vagina. The patient had very severe labor pains, the os was dilated about two fingers and he found the uterus to be as large as a six months' pregnancy. He removed half a pailful of the cysts of a hydatidiform mole. On being emptied the uterus contracted and the bleeding was partly checked. The patient was sent to Gouverneur Hospital for further treatment. On admission to the hospital, August 7, 1901, examination showed the uterus to be large and

soft, os dilated and bleeding from cavity. Temperature 100° F.; pulse 120; respiration 32. On that same day, under ether, Dr. Bradner, the house surgeon, curetted her, bringing out a few small cysts with some shreds. The uterus was then irrigated with saline solution and packed. The patient was returned to the ward in good condition. She did well and was discharged August 23, 1901. She returned September 5, 1901, complaining of pain over the uterus; upon examination the uterus was found to be enlarged and very soft, and bleeding slightly. She was put on tonics, ergot and douches, and an ice-bag was applied over the uterus. As the bleeding, though very slight, continued, Dr. Bradner again curetted the uterus on September 10, 1901. There was very little to remove. The uterus was then irrigated and packed and the patient returned to the ward in good condition. She was given ergot, ½ dram, q. 4 h., strychnine gr. 1/30, t.i.d., and a hot bichloride douche, b.i.d. This reduced the size of the uterus somewhat, but the flabbiness still continued. She looked anemic and all her tissues were flabby; but under the administration of iron she improved and was discharged September 29, 1901.

During the night of October 3d she was again seized with a severe uterine hemorrhage and Dr. Friedman was hurriedly called. He tamponed her and sent her to Gouverneur Hospital. The patient was examined for the first time on the morning of October 4th. Heart and chest were normal; she was very anemic; all the muscles were flabby and the skin slightly edematous. Bimanual examination revealed an ovarian cystoma about the size of a cocoanut on either side. The uterus was in the normal position, but considerably enlarged. Its walls, as well as that of the cervix, were very much thickened, soft and congested. The os was patulous and there was a moderate amount of hemorrhage from the uterine cavity. The consistency of the uterus was neither the soft feel of subinvolution, nor the elastic resistance obtained in incomplete abortion. It was rather that of a chronic hyperplasia. On the posterior wall, near the left border and close to the cornu was a small elevated nodule about the size of a ten-cent piece. It was so intimately connected with the endometrium and the uterine wall that it appeared to be a slight projection of the uterine muscle. It could not be separated or lifted up from the endometrium with the finger-nail, as is the case with adherent placenta. It was soft, friable, spongy, and bled freely on touch. On manipulation the finger broke easily through its apex and penetrated the uterine wall, which at that point was soft and friable, almost to the peritoneal surface. The history of the patient and the general condition was certainly very suspicious; but the presence of the nodule made the diagnosis of deciduoma malignum absolute. The only other conditions to be considered were an adherent portion of placenta and a partial perforation of the uterine wall, made at one of the previous curettings. In that case both the base and the edges of the uterine wound would consist of normal uterine tissue. The next day, under ether anesthesia, in the presence of Drs. Huber and J. Rogers, abdominal hysterectomy was performed. The patient made an uneventful recovery.

The histology and pathology of deciduoma malignum is still a subject for discussion and controversy among pathologists. Some consider it as belonging to the sarcomata, others to the carcinomata; a few writers maintain that it is of maternal origin, while the majority hold that it is of fetal origin.

The clinical features which should invariably establish the diagnosis are as follows: (1) The history of recent parturition or abortion, especially the discharge of a hydatid mole; (2) profuse hemorrhages occurring at irregular intervals, especially if recurring in spite of repeated curettages; (3) anemia, rapid loss of flesh and strength; (4) persistently large and soft uterus and cervix; (5) pain in pelvis; (6) these symptoms call for a digital exploration of the uterine cavity, and when the characteristic nodule is discovered the diagnosis is established beyond a doubt; (7) metastasis occurs very soon after the appearance of the primary focus.

The microscope will only corroborate the diagnosis; it may even fail to make the diagnosis in the early stage when it can be made by digital exploration. Curettage when the nodule is small may only bring away blood clots and shreds which show nothing characteristic.

Dr. Jeffries said that he was surprised when Dr. Ladinski came in with the specimen and said that he had a case of deciduoma malignum and wanted to have a section of it. He expected when pathological specimens were brought to the laboratory to be asked what they were, and when he presented a specimen of the rarity of this one, and had made his diagnosis before the operation he thought he had done a little more than usual. The number of cases that have been described is very limited. The first described was in the fifties. At Johns Hopkins there is a small list collected by Dr. Williams. Are they of fetal or maternal origin? The consensus of opinion is that they are derived from the syncytium, and it is not known whether the synctium belongs to the embryo or the maternal tissues.

Initial Lesion of Tongue.—Dr. D. A. Sinclair showed a patient with an initial lesion which is not very rare but sufficiently so to be of value to those who are interested in genito-urinary diseases. He came for examination about two weeks ago complaining of a soreness in his mouth and upon examination it was evident he had an initial lesion of the tongue. It happens about once in a hundred times. This is sometimes mistaken for epithelioma, but the age of the patient and the presence of secondary symptoms confirm the diagnosis.

Regeneration of Radius.—Dr. Bodine presented a case of regeneration of the radius following its removal from the wrist to the elbow following a Colles' fracture. The child, a little street Arab, was in perfect health, when he broke his arm. He went to a dispensary and the arm was put up and a dressing covering the entire hand was applied. Between his fingers there were particles of dirt and fermentation occurred between the fingers. On account of the pain and fever his mother brought him to the Northwestern Dispensary. There were two lines of lymphangitis up the back of the arm in which sixteen different incisions were made. This cellulitis started from uncleanliness between the fingers. The bone was taken out in two pieces. The result is a hand with which he can perform every motion as easily as with the other.

Dr. Bodine also reported a case of regeneration of the lower jaw following the removal of one-half for necrosis. The jaw was taken out from within the mouth—a perfectly feasible operation. He had done it twenty-seven times and not more than a teaspoonful of blood had been lost during the operation. The result is a perfect jaw with the exception of teeth.

ORIGINAL ARTICLES.

CHRONIC MYOCARDITIS.[1]

I. MORBID ANATOMY AND PHYSICAL SIGNS.

BY J. H. MUSSER, M.D.,
OF PHILADELPHIA.

THE more recent studies of cardiac pathology impress one more and more with the force of the old term *morbus cordis,* employed in a generic sense to include the phenomena of chronic cardiac disease. Indeed, Laennec was not far from the truth, in a clinical sense, although not quite correct in his pathology, when he devoted six chapters of his work to hypertrophy and dilatation, five to atrophy, softening, induration and fatty degeneration, and one only to valvular disease. When you think of it, if the heart muscle is healthy, chronic valvulitis yields but few symptoms. If the former structure meets the physiological demands required by the valvulitis, in most lesions no symptoms arise. Valvulitis of the aortic leaflets, admitting regurgitation, is the only lesion which may cause symptoms independent of the state of the myocardium. While the chronic valvulitis may exist for a life-time with a minimum symptomatology, yet in striking contrast we see chronic disease of the anatomically associated structure—the myocardium—with a most complex pathology and symptomatology. It is not common to have chronic myocarditis, without some hypertrophy, dilatation, atrophy, fatty degeneration or infiltration, singly or combined, or to have any of the latter conditions without myocarditis. In consequence the symptoms of myocarditis are intermingled with those due to other mural changes. Such mingling of pathological conditions must imply a common fundamental causation. Such we see in the state of the pericardium (local myocarditis) or of the coronary arteries (fibrous myocarditis), on the one hand, or, on the other hand, in varying conditions dependent upon intracardiac pressure (myocarditis with dilatation after valvulitis, emphysema or nephritis), or upon the nutritional value of the blood (myocarditis of anemia with fatty degeneration—the fatty heart), or upon the direct but general action of infectious or toxic agencies (parenchymatous myocarditis).

Myocarditis after pericarditis is exemplified in the case of A. E., aged sixty-three years.[2] Heart enlarged; weight 19 ounces; enormous amount of pericardial fat, and distinct chronic pericarditis, there being firm adhesions, nearly obliterating the sac. Hypertrophy is general, the right ventricle being considerably thickened. Aortic valves thickened, with dilatation approaching valvular aneurisms. Mitral valve also much thickened, stiffened and dilated. No calcification. Aorta normal. Tricuspid valve decidedly dilated. Heart muscle flabby, containing some white patches, suggestive of fatty metamorphosis. Cavities decidedly dilated.

Myocarditis with dilatation is frequently seen as the terminal event in cases of chronic lung disease, as emphysema (right heart), or of chronic nephritis or of arteriosclerosis. It was typically seen in the case from which the specimens to be described were removed.

Dilatation of Heart.—A. L., aged fifty-nine years. Heart, in pericardium, extended in fourth interspace from nipple line on right to two inches beyond left nipple in fifth interspace. Pericardial sac contained about the normal amount of fluid. Heart weighed 28 ounces. There was enlargement of both sides. The veins over surface were distended. The cavities were filled with antemortem clots extending into the vessels. Over the right ventricle there was a milky-white patch about three inches in diameter; over the apex another similar patch the size of a quarter of a dollar. The left ventricle was more than one inch in thickness. The muscle was pale red, quite soft and fatty. The papillary muscle was hypertrophied. The anterior muscle was fully half an inch in breadth at base. Tips were fibroid. Chordæ tendineæ thickened and contracted. The cavity was dilated, four fingers being admitted into valves. The right cavity was enormously dilated. The tricuspid admitted four fingers. The muscles were soft, pale and fatty. The fatty degeneration was not uniform, but in various areas. All the papillary muscles were hypertrophied. The mitral valves were thickened at edges. The bases were surrounded by a ring of atheroma (calcareous) of irregular thickness in continuity. The aortic valves were extensively diseased; the inter-coronary leaflets thickened along edges and at base. The coronary arteries were free from atheroma, except at the mouths, which were dilated.

The remarkable changes in the heart muscle seen in pernicious anemia are too well known to require description, as also are the appearances of parenchymatous myocarditis.

Fibroid Heart.—Far more frequently we find myocarditis, either local or general, the result of coronary artery disease. It was well seen in a case which presented the typical fibroid heart. T. L., aged eighty-one years. The heart was large, without much subpericardial fat. Recent patch of pericardial thickening was seen over apex. Right ventricle enlarged and contained antemortem clot. Muscle very hard, red and

[1] Read in part before the New York Academy of Medicine, and in part before the Virgina State Medical Society.

[2] For microscopical report of the cases reported herein, see Musser and Steel, Trans. Phila. Path. Soc., Feb., 1898, Vol. I., New Series.

firm. Left ventricle hypertrophied at base, 1¼ inches thick; at apex ½ inch thick, tapering. Papillary muscle of anterior cusp thickened, hypertrophied and fibroid at tip. Fibrous substance extends far up the chordæ tendineæ. Papillary muscle of posterior cusp short, thick and fibroid. Mitral valves slightly thickened and atheromatous. Muscle of left ventricle pale, firm and not fatty. Aortic valves thickened at edges but competent. Aorta the seat of extreme atheroma lined by calcareous flakes. Both coronary arteries atheromatous. Valves of right heart normal. Aorta extremely dilated in ascending portion.

Local Myocarditis.—In the following the appearances were even more striking. R. B., aged fifty-eight years. Heart was enlarged and weighed 20 ounces. Cavities were dilated. In left ventricle, old thrombi were adherent to walls, and there was a recent clot. Papillary muscles enlarged. Slightly fibrous tips, otherwise presenting but little degeneration. Vessels in papillary muscles very distinct, undoubtedly enlarged in caliber. Underneath papillary tip in substance of muscle was a dark red area. Muscle at left apex pale red, mottled yellow, rather firm material. These areas of yellow fibrous matter in the ventricle were next to the cavity, and usually most pronounced when opposite thrombi. Anterior ventricular septum much thickened, very firm and on section presented yellowish areas alternating with dark red, with normal muscle interwoven. The papillary muscle of the anterior cusp presented the greatest change. Left auricle dilated moderately. Mitral valve admitted three fingers. Some areas of atheroma. The tricuspid orifice was enormously dilated; valve normal. Papillary muscle presented some yellowish-white fibrous change. Muscle was firm, mottled in areas, presenting the most marked change below the pulmonary valves. Auricle much dilated; cavity enlarged and much hypertrophied. Some opacity at base of tricuspid and undoubted degenerative changes. Anterior coronary artery markedly atheromatous, presenting a recent antemortem clot and an old thrombus, which evidently occluded the vessel largely about one inch from its origin. Surface of heart presented dark red or normal color and light red areas, alternating with yellowish mottling. This area was over the surface of the left ventricle, two inches wide, extending from the base to the apex. It appeared to include that portion supplied by the vessel which was the seat of thrombus. The auricular appendix presented marked areas of yellowish-white fibroid degeneration. Orifice of posterior coronary somewhat occluded, not, however, presenting so rigid and marked appearance. Fat along this artery was abundant, while along other branches markedly lessened. No thrombi in the lumen of the large veins. Marked and most prominent degenerative changes were seen in the muscles, independent of the fat. Aortic valves normal. Aorta atheromatous throughout entire course.

Local Fibrous Myocarditis.—Or again we see in arteriosclerosis the following appearances of local fibrous myocarditis. J. H., aged eighty-six years. Heart weighed 16 ounces. Left ventricle three-quarters inch in thickness and apex one-eighth inch thick. Color red, with soft subendocardial staining. Papillary muscle rather small. Fibrous at the tips; yellowish color at points. Areas quite marked on section of the muscle. No "tabby-cat" striations of muscles. Chordæ tendineæ short and thick. Mitral leaflets thick. Edges indurated, but not calcareous. Competent valves. Aortic valve thickened. Corpora not enlarged. Some thickening across middle valve. Base of valves atheromatous. Coronary pouch quite dilated; valves apparently dilated. Aorta dilated, with some atheroma. Coronary artery (right) dilated; walls thickened. In the middle of the artery there is a patch of atheroma (calcareous) half an inch long. Artery seems to be wider below than above. Left coronary artery walls thickened. No atheromatous patches. Right ventricle walls thin and soft. On section from the middle of the cavity to apex in center of muscle is seen a buff-colored leathery line averaging one-sixteenth inch in thickness, more marked toward the apex. A number of the papillary muscles in apex are yellow in color, and on section show fatty appearance. The left ventricle is one-eighth inch in thickness. The cavity is dilated.

Leaflets of posterior coronary valve are thickened at margin and are atheromatous; more on the anterior. The muscles are not dilated. The muscle is fatty and fibrous on section. Left auricular endocardium is thick and dull. The muscle is pale yellow in color. In appearance the walls are leathery, being wrinkled and tough. Chicken-fat clots were found in the ventricles and extended into the vessels. The cavity of the left ventricle was dilated. Atheroma of aorta extended throughout its course. It was observed in internal mammary, renal and colon areas. Further examination not made.

Myocarditis and Valvulitis.—The degenerative changes seen in the heart with valvulitis were well exemplified in the following case. W. H., aged twenty-four years. Heart enlarged; left ventricle hypertrophied. Muscle firm. Same appearance in intraventricular septum of fibroid change as just described. Papillary muscle small. Fibroid at left. Chordæ tendineæ contracted. Mitral orifice admits two fingers very readily. Mitral valves are thickened, atheromatous. The aortic valves contain a few atheromatous patches, particularly at the base. The coronary arteries are atheromatous, elongated and twisted. The aorta is dilated in ascending portion throughout the seat of extensive atheroma.

Local myocarditis was found in the following cases:

Local Myocarditis and Valvulitis.—J. P., aged seventy-six years. Heart weighed 25½ ounces. Right side flaccid. Right auricle contained about three ounces of pure blood. Left side flaccid. Auricle contained about three ounces of blood, ventricle about four ounces of fluid blood. The walls of right ventricle slightly thickened. Ven-

tricle contained about five ounces of fluid blood. The walls of left ventricle were somewhat thickened and in the lower posterior portion, near the apex, an area one inch in diameter and extending nearly through the thickness of the wall was white and fibroid. The pericardium, particularly in left side, was thickened and showed scattered white spots, about one-quarter to three-eighths inch in diameter. The aortic valve, calcareous and slightly incompetent. Atheroma of coronary arteries. Aorta atheromatous, containing calcareous particles.

Local Myocarditis.—J. R., aged forty-nine years. Left cavities filled with soft black clots. Left ventricle firmly contracted and hard. Right auricle contains yellow clot, some black clot and fluid blood and is distinctly enlarged. The valves of the right side of the heart are normal. The Eustachian valve shows distinctly. The coronary sinus will easily admit a small finger, and does not show any valves. There is no opening through the fossa ovalis. The muscle of the right heart is unusually firm, 12 mm. thick, pale in color; papillary muscles are mottled. The left auricle is normal. The mitral valve is somewhat thickened along the edge but not retracted The anterior surface of the anterior leaflet of the mitral valve shows several patches of atheromatous infiltration. The left aortic valve shows a patch of calcareous infiltration at its base. The other aortic leaflets are normal. There are many small patches of atheromatous infiltration around the sinus of Valsalva and around the coronary arteries. The muscle of the left ventricle is about 23 mm. in thickness. The color of the outer portion of the muscle is brown; the deeper layers are yellow. The papillary muscles are mottled and very pale at tip. The muscle of the left ventricle is not enlarged. The coronary arteries are extremely atheromatous. Weight 18 ounces.

Time forbids allusion to the clinical course of the various forms of myocarditis just referred to. What has just been said of the complexity of the phenomena can be appreciated by noting the following: (*a*) Myocarditis secondary to pericarditis has the symptoms of dilatation or of dilated hypertrophy and sometimes of that curious group of symptoms associated with mediastinitis, hepatitis and splenitis in which the predominate or unequivocal symptoms are hepatic and splenic, with ascites; (*b*) myocarditis following valvulitis or peripheral obstructions (lung or kidneys) is associated with symptoms of dilatation; herewith are intertwined, on the one hand, the symptoms of emphysema or nephritis; or, on the other hand, those of valvulitis; the physical signs of the latter condition obtain; it is most difficult often to go beyond the diagnosis of dilatation of the heart; (*c*) myocarditis of toxic and anemic origin; the fatty heart is associated with symptoms of grave secondary or pernicious anemia or of toxemias, as from tobacco or mineral poisoning or from chronic infections; (*d*) fibrous myocarditis—coronary artery disease.

It is to the clinical expressions of this form of myocarditis I beg leave to call your attention. In the description of the lesions it may have been observed that most of the patients were old subjects, and hence I gave to you an anatomical account of the senile heart—the fibroid heart. Clinically cases of senile or fibroid heart are so mingled with the other phenomena of senility that we are not wont to ascribe the symptoms to the cardiac lesion more than to the associate degenerative lesions of other organs of the body. Moreover, the vegetative inactive life led especially by those who become inmates of infirmaries dulls the sensibilities, reduces the vascular strain or tension to a minimum and hence effaces or obliterates most of the phenomena of myocarditis.

That form of chronic myocarditis which comes home to us more forcefully is the one seen in subjects just past the prime of life—mostly in males. Their career has been one of active strife, of the surmounting of difficulties. They have usually been accustomed to the good things of the earth and perhaps have been victims of early syphilitic infection.

March 9, 1898, I was consulted by T. W., manufacturer, aged fifty-eight years; married; has children. Uses tobacco and stimulants moderately. Father died of old age at ninety-three, mother died at eighty-seven, brother died four years ago. Patient's general health always good until present trouble. Never had rheumatism or gout. Prior to six years ago worked very hard. One year ago began to suffer from oppression or accumulation of mucus requiring cough; gradual increase in difficulty of breathing and past few months oppression or weight on heart. At present, smothering at night, necessitating sitting up in bed. Past year, swelling about ankles at night. Coughs in morning to raise mucus (sticky). Appetite good; no indigestion; gaining in weight, now 240 lbs., but is losing strength. Bowels regular. Feels languid and has dyspnea on slight exertion. Is prematurely old. High-tension pulse. Artery elongated. Marked accentuated aortic second; uncertain murmur at second aortic. Heart's impulse not seen or felt. Apex sound loudest at fifth interspace. Both tricuspid and mitral are feeble. Color pale on exertion. Hands dusky.

March 14th: Tired in morning; wants to sleep on reading.

March 21st: Pain and weight better. Can breathe much more freely. Sleeps without smothering at night. Pulse 96.

October 1, 1897. J. H. J., merchant; aged fifty-five years; married; no children. Until three years ago was an inveterate smoker. Uses no stimulants. Formerly used coffee; now none. No unusual hours of wakefulness. Meals regular. Fast eater and drinks much water. Syphilis in 1863, primary and secondary. Has not been South or exposed to malaria. No acute disease. Had bilious attacks. Father died of bilious trouble, aged seventy-two. Mother died as result of accident. One sister living and healthy. One brother died of consumption of bowels. Two and

a half years ago continuous headache, which seemed to affect memory, partly occipital and partly frontal. This headache continued one and a half years. One dose of bromocaffeine would relieve. Irregular as to time of day in severity; not increased by any known cause. Nine months ago began to be short of breath. In July very bad, but now better. Dyspnea increased by walking and ascending stairs, but can ride wheel. The oppression occupies a circle about eight inches; not worse after food. Weight formerly 200, now 180; reduced by disease. Appetite fair; no nausea. Discomfort two hours after eating. No flatulency, but dull heavy pain, with desire to sit up straight. Dyspnea not worse after eating. No palpitation; no fainting.

Physical examination showed patient to be somewhat pale, with sallowness; said to be natural. Flabby. No scars; no eruption. Heart a little to left. Apex feeble. Impulse feeble in fifth interspace inside nipple line. Not enlarged upward. Gallop rhythm and slight intermittency and irregularity. Accentuated second aortic greater when standing up. Gallop rhythm greater with recumbent posture. High arterial tension. No venous phenomena.

November 28, 1897. Until yesterday quite comfortable. Past twenty-four hours some shortness of breath and gastric disturbances. Color better; strength better. Occasionally some dyspnea, but not so frequently as formerly. Does not rise to pass water. Muscular sounds of heart better. No accentuation. Some muscular pain in chest. On talking or reading gets distress in chest; has to stop on account thereof.

December 8, 1897. More dyspnea past week. Last twenty-four hours pain and soreness in chest. On physical examination liver still large. Heart's action feeble and irregular with high tension and gallop rhythm. Bowels irregular as to character. Some headache and oppression. No enlarged glands.

December 13, 1897. Liver not tender now.

January 19, 1898. Numbness in arms and feeling as if going to drop off, from elbows down; begins shortly after exertion and stops as soon as walks.

February 2, 1898. Heart irregular. Dyspnea considerable.

February 16, 1898. Heart regular. Dyspnea continues. Some numbness. Apex outside middle clavicular line. Mitral and tricuspid murmur, and gallop rhythm at apex.

March 10, 1898. Death from apoplexy.

The form of chronic myocarditis that occurs at this period of life has some special clinical expressions too often not referred to the heart. Some of them have "pain" for their most prominent symptom; in others "dyspnea" is the most severe; in others syncopal or apoplectiform attacks and the curious Stokes-Adams syndrome. In still others, distressing arhythmia occurs. While more or less special symptoms pertain to each individual, the physical appearance and the physical signs are common to all.

Physical Signs.—Of these most common is the sallow pallid countenance. This is most striking. Rarely can you be wrong in the inference, when such persons present themselves, that the endarteritis has involved the coronary artery and that the myocardium is off. A general endarteritis may be present for a long time and yet no change occur in the complexion. Interstitial nephritis I have seen progress slowly, and yet no change in the complexion. The onset of this hue is generally synchronous with the degenerative cardiac lesion and usually cardiac symptoms or physical signs are found coincidently; the endarteritis involving the coronary arteries.

With the sallow countenance, the earthy complexion, a prematurely old appearance of the individual manifests itself, in the color of the hair, the baggy eyelids and the abundance of wrinkles.

With the external appearance common to most cases the results of physical examination usually tally. In the first place there is evidence of endarteritis in the vessels. The palpable, often tortuous vessels show thick walls and high tension. The temporal arteries are prominent and we have the other indication of degeneration, the *arcus senilis*.

The physical signs of the heart are those of the (*a*) myocarditis alone, or those of (*b*) myocarditis plus some hypertrophy, or those of (*c*) myocarditis plus dilatation. The physical signs of myocarditis are those of feeble or absent impulse; or, if palpable, of apex impulse displaced to the left; of marked increase in the area of absolute cardiac dulness and of characteristic auscultatory phenomena.

The latter phenomena are those either of a systolic shock, greater than the force of the impulse would lead us to believe to be present, or of feeble muscular sound. In the early stages the former exists, and it continues later if hypertrophy co-exists. From the first, or at least early, we have gallop rhythm, or reduplication of the systolic sounds. This reduplication may be heard over the right heart or more distinctly over the left heart; sometimes it is heard all over the precordia. My impression is it is more commonly heard in the parasternal line at about the fourth rib. It may be more marked in the supine position and is generally more marked after exertion. It may disappear after a stimulant is taken or if the heart is stimulated by fever. Reduplication of the second sound also obtains, but is less frequent in the myocarditis of coronary artery disease than in that due to valvulitis or nephritis. In uncomplicated cases murmurs are not heard until late in the disease. Sometimes, however, we hear a systolic murmur at the fourth rib, greater in the recumbent posture. This murmur is soft, low in pitch and so often heard in the parasternal line that it is my custom to call this line the myocardial line. Again, it is at the tricuspid or even may be in the pulmonary area—when it is probably, although not necessarily, hemic.

My studies have not followed so closely and

exhaustively as their importance demands the brilliant observations of Sewell. I cannot help but think with him the papillary muscles are the source of the auscultatory phenomena of myocarditis whereby leaflets do not coapt synchronously, or areas of the muscle synchronously contract.

When dilatation supervenes, if it does, the physical signs change in keeping with the physical condition of the heart. Here however, the auscultatory signs of insufficiency at the mitral and tricuspid orifices are predominant, rarely at the aortic; accentuation of the pulmonary second sound is a frequent sign, with low tension pulse and engorgement of the venous side of the circulation.

The pulse is like that of endarteritis. The artery is readily palpable, isolated with ease, showing high tension, and while apparently strong because of a quality of fulness which with the hard vessel gives a feeling of strength, it is actually feeble. The arteries are fibrous but not necessarily atheromatous. Indeed, the patient with pronounced atheroma will probably not have symptoms at least of endarteritis and will die of cerebral thrombosis or of senility alone, or of intercurrent or terminal infections. Our middle-aged patient with endarteritis does not necessarily end with advanced atheroma, but dies of apoplexy, nephritis, angina or sudden heart asystole.

The myocarditic heart of fatty degeneration—the fatty heart—presents some similar signs. A visible impulse is wanting and any palpable impulse is felt as a slap against the chest wall. The area of dulness is normal or slightly increased; a loud hemic murmur at any orifice, but most frequently at pulmonary and aortic valve, may be heard. Just as frequently the sounds are almost inaudible, the second sound at the base alone is conducted to the ear. There is pulsation of the vessels.

We may say, then, that myocarditis may exist (1) without definite physical signs—a rare occurrence I believe; (2) with signs of moderate cardiac hypertrophy, marked reduplication being the only physical sign and of significance only when coupled with signs of endarteritis; (3) with physical signs of dilatation; (4) with physical signs of fatty degeneration; (5) with the physical signs mentioned, which in the aggregate are of great significance.

PROLONGED MEDICATION, WITH SPECIAL REFERENCE TO DIGITALIS.

BY ABRAHAM JACOBI, M.D., LL.D.,
OF NEW YORK.

SEVERAL meetings of the German Congress of Internal Medicine have discussed the effects of digitalis when given continuously for a long time. That question was also raised in a recent discussion, mainly by Dr. Robert Ingram and Dr. Frank Scherer, before the Academy of Medicine of Cincinnati.

The woful stories of its cumulative action were told and retold. Indeed, I dare say that there is no careful or careless practitioner that has not observed it; there may be nausea, vomiting, retarded or irregular pulse, and collapse. When I was young I saw it often, mainly after large and repeated doses, and remember well that I believed that I obtained a salutary effect—in pneumonia, for instance—from that very action. But after all time has taught me several things. I now know, for instance, and have acted on that knowledge for more than a decade, that in many bad cases of dilatation of the right heart, with cyanosis and orthopnea, when nothing but a large venesection appears to hold out a promise, one, two or three doses each of ten or twelve grains of digitalis, given at intervals of three or five hours, will contract the heart and restore pulmonary and general circulation; that, on the other hand, in chronic conditions of weak heart, of either muscular or nervous origin, or of insufficient action caused by pulmonary obstruction—as in chronic bronchopneumonia or in tuberculous infiltration—small doses of digitalis, that is, from 4 to 6 grains (0.3-0.4) daily, or its equivalent, may be given for weeks and months and even years without any hesitation. Such doses may be ordered while the patient is not expected to be seen for weeks or months. Indeed, there is hardly a day when I am not obliged to prescribe them to patients who I know will not reappear for a month or more. In most cases I prescribe either from four to six doses daily of Squibb's or any other good fluid extract, or the solid extract of the Pharmacopœia in the shape of pills, 1½ grain (0.1) daily, usually ½ grain three times a day, almost always in pills, rarely by itself, often in combination with sparteine, or strychnine, or arsenic or other drugs, as the case may require. Such combinations are generally observed to be useful, as nosologically they are required by the fact that the heart is not a uniform body but a combination of muscular, vascular, and cerebrospinal and sympathetic nerve fibers; that we have but rarely to deal with an affection of only one of them, and that the theoretical demand of only one remedy in a prescription looks well on a platform, as the ornamental trimming of an impressive address to the young, but gives one but a poor show at the bedside.

Patients who take digitalis in this way do not show a cumulative effect, nor are they getting accustomed to it to such an extent as to lose the benefit of its action. Indeed, their heart requires a daily stimulation and daily doses. Mercury is given for months, iodides for months, not only in syphilis but in the cardiac ailments of atheromatous old age where digitalis is not tolerated, and in asthmatic conditions. Arsenic is administered in psoriasis, lymphomatosis and sarcomatosis for months and years with rarely an interruption unless the doses be excessive. Phosphorus demands a course of six or eight weeks to break up a bad case of rhachitis. Thyroid, thymus, or suprarenal gland is required for many months or even years to accomplish the end in view. Every-

body knows that and should add digitalis to the list of his drugs that ask for continued small doses when a continued effect is expected.

This looks so simple and *is* so simple that I never knew these thirty or forty years that I did anything which required discussion. During all this time I practised this method, taught it and mentioned it in papers, for instance, in one on "Arsenic and Digitalis in the Treatment of Consumption," read before the New York State Medical Society in 1884. Great, therefore, was my astonishment when before the Seventeenth Congress for Internal Medicine, two years ago (1899), Dr. Grödel of Nauheim spoke in favor of continued small doses of digitalis in appropriate cases. He was frowned down by most of the celebrities present, but soon Kussmaul[1] published his cases of continued digitalis treatment, and he is not usually frowned down. Thus it happened that this year public opinion veered rather in the direction of Grödel's position on that question, mostly with the understanding, however, that a careful watch must be had over the patient. When the observations of the past two years will have been confirmed by those of the next ten, that careful watch will be discontinued as unnecessary.

In my paper read before you in 1884 I discussed the effect of small doses of digitalis continued a long time and their action in pulmonary phthisis. I then spoke as follows: "In the vertebrate, digitalis increases the energy of the heart muscle and the volume of its contraction. Thereby it increases arterial pressure and diminishes the frequency of the pulse. In this connection it is of no consequence whether the irritation of the inhibitory nerve is the primary or the secondary element. By increasing pressure in the arteries, besides favoring the secretion of the kidneys, it improves the pulmonary circulation, empties the veins and thereby accelerates the circulation of the lymph and tissue fluids. Thus, while having an immediate effect upon the heart and lungs, it exerts a powerful influence on assimilation and elimination, that is, nutrition in general.

"Therefore, both the local and general effect of digitalis are invaluable in all stages of phthisis. While, however, they may relieve in the last, they are a healing element in the first stages; the congestive and nutritive changes constituting the preparatory and, in part, the advanced stages of consumption are favorably influenced. I seldom treat a case of pulmonary tuberculosis without it. Very little care is required to avoid disagreeable results. Cumulative effects are either the consequence of excessive or too frequent—unnecessarily frequent—doses, or of the selection of improper preparations. Such, however, as are soluble in water with difficulty ought not to be used, for it may happen that, having been inert for some time, a large amount may enter the circulation at once. Particularly is this true of digitalin, which is by no means a soluble alkaloid, but a crystallizable glucoside of uncertain strength. The digitalins of different manufacturers yield widely differing results; the majority require immense doses compared with the dictates of the books in order to exhibit a perceptible effect. I use the infusion, the tincture, the fluid extract, and the solid extract. Their relative values I do not desire to discuss, except in regard to their advisability in phthisis, and the possibility of continuing them for a long time. Patients of that class we see from time to time only; they require advice and prescription for protracted periods. As a rule their digestive organs are amongst the first to suffer; indeed, many an alleged dyspeptic patient is afflicted with gastric disturbances first, and has his attention drawn to the lungs by his physician, who discovers the cause of his gastric catarrh in the retarded circulation of heart and lungs.

"In such a case the stomach exhibits the peripherous symptoms of the distant diseased organs in the same manner that a local disease of the brain or cord shows itself first in affections of peripherous nerves. Now, whenever the stomach is first affected neither the tincture nor the infusion is tolerated long. The latter, the officinal preparation, may be given three times daily in doses of half a tablespoonful each, or in two of three teaspoonfuls each, for some time; but I seldom wish to recommend it for more than four or five days in succession without seeing the patient. The fluid extract has often disappointed me; I cannot tell why, nor do I claim to know why. [That is what I said sixteen years ago; I can now say after daily observation extending over many years, I have learned to rely on Squibb's and some other fluid extracts.] My main reliance is on the solid extract and my almost universal method of giving it is in the form of a pill, in such combinations as will suit the individual case. The stomach does not object to it and taste is not offended by it. I often prescribe 1½ to 1¾ grains, corresponding to three and a half times its weight of digitalis, for weeks without expecting to see the case again. It combines with extract of nux vomica, with iron, with arsenic, with extract of belladonna, or extract of physostigma (Calabar bean), with ext. coloc. compound—in fact, with anything. Such combinations are frequently required in the early stages of consumption. The general muscular system needs toning up, the intestinal muscle requires strengthening, the intestinal tract evacuation, the intestinal and abdominal circulation easing. At the same time, iron may be added when there is no fever; or caffeine for its stimulant effect upon the heart and arteries."

Speaking as a general practitioner before a meeting composed almost exclusively of general practitioners, I desire to add in this connection a single remark on the general usefulness of digitalis in other cases. Every chronic disease and the results of the wear and tear of what is called civilized life have a depressing influence on all parts of the organism. The heart is not the last

[1] Therapie der Gegenwart, 1900, No. 1.

to suffer. Its muscular strength is tasked every second; it is the very organ that cannot and must not rest. Stagnation in an outlying province will overexert it; ill nutrition of the nerves will influence it, general anemia exhaust it, infection paralyze it, weak circulation or venous obstruction interfere with its structure and strength.

Now, what alcohol and ether are to the nerves, strychnine to the muscles in general, digitalis is to the heart, except in a condition of acute myocarditis. The increase of arterial pressure which it produces is beneficial not only to the outlying provinces, but also to the circulation and nutrition of the heart muscle itself. Thus, in all cases of general anemia, in slow convalescence where iron and nux vomica are called for, digitalis is likewise required. It strengthens the heart, propels the blood stagnating in its own fibers, and shortens the period of recovery. I have learned to look upon digitalis for restoring vigor and strength as of more than mere symptomatic value; I consider it one of the best tonics, along with iron, nux and arsenic, when given in small doses persistently.

The main effect of digitalis is the increase of cardiac contraction and of the volume of the pulse. Both are, according to Schmiedeberg, caused by the improved elasticity of the heart muscle and its more intense shortening during systole. The concomitant result is an improved action in diastole, for a heart that is thoroughly emptied during systole is better qualified to aspirate a new supply. The retardation of the heartbeat resulting from the stimulation of the pneumogastric nerve through the action of digitalis allows opportunity for the complete emptying of the ventricle with consecutive improved aspiration; in other words, the arterial blood-pressure and circulation are increased and afford the veins ample opportunity to discharge their contents. That is the effect of large doses of digitalis given once or oftener. To give big doses too often may lead to the exhibition of one or more of its bad effects, the so-called cumulation. Large doses, however, are not required for long, but many cardiac diseases demand moderate doses for moderate effect; more still require a persistent effect for the symptoms caused by anatomical lesions which cannot be removed. It is these that cause a persistent moderate incompetency of the action of the heart, which can be dealt with only by just as persistent moderate doses of the proper remedy. Years of cardiac ailment should be met by years of cardiac medication. This is intelligible to those who will be good enough to consider that insufficient metabolism and the hunger of the tissues can be treated only by persistent feeding, say three or four times daily, and not by the pouring in of a dozen beefsteaks at a time with fasting afterward.

The small doses which I recommend as the regular daily measure have only a moderate action on the blood-vessels. That is important to know, because large doses may contract the small arteries to such an extent as to increase the labor the heart has to undergo to overcome the increased peripheral resistance.

The indications for the use of digitalis according to the methods just indicated are the insufficiency of the heart muscle and the incompetency of the mitral valve. Chronic myocarditis is no contra-indication. Large doses may overexert the inflamed muscle; that is why digitalis in large doses is very badly borne in *acute* myocarditis; small ones are often serviceable when the first onset is passed. Aortic insufficiency has been declared a contra-indication to digitalis by some, an indication by others. I feel certain that these observers had different cases to deal with. Aortic insufficiency, when incipient or moderate, is easily compensated, gives no uneasiness to the patient, is not complained of, and is seldom observed when recent. This is the time when such doses of digitalis continued a long time prove of permanent service. Only those, however, can be thus benefited whose cases are recognized early, either accidentally or through careful self-observation by the patient. When, however, the case is old and compensation greatly disturbed, with considerable peripheral venous obstruction, even digitalis will not suffice to restore the equilibrium between the action of the heart and the capillary circulation of distant organs.

A last word on one form of incompetent metabolism with which we frequently have dealings, namely, chlorosis. I never treat it without adding digitalis to the iron and the mild vegetable purgative the patient is to take. Its influence on the circulation of the body in general and the heart vessels in particular is such as to improve general and local nutrition for reasons detailed before. All forms of chlorosis are benefited by it, the common as well as the severe form pictured by Virchow and Germain Sée. In this, while the heart may be normal in size but is generally of feeble structure, the arteries are small and do not provide for a sufficient organic nutrition. It will be easily perceived how the action of digitalis in small doses, persistently given, cannot help but be beneficial.

HEART STRAIN: ITS RESULT AND TREATMENT.[1]

J. M. G. CARTER, M.D., D.SC., PH.D.,

OF WAUKEGAN, ILL.;

EMERITUS PROFESSOR OF CLINICAL MEDICINE, UNIVERSITY OF ILLINOIS (COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO); MEMBER OF AMERICAN MEDICAL ASSOCIATION.

THE study of heart strain and cardiac conditions referred to heart stress is of comparatively recent date. British surgeons serving in India discovered that dilatation often occurred among soldiers, and Watson, in his lectures, expressed the opinion that it is more common in civil life than was usually supposed; but it was not until later that mechanical strain was recognized as a cause. As late as 1871 Allbutt made the remark that "mechanical causation of heart disease is either omitted, or is treated in a way so meager

[1] Read before the Illinois State Medical Society, May 21, 1901.

as to be worthless, by the European and foreign writers."

The first studies in this direction reported in the United States, so far as I am aware, were made during the war of 1861-65. Dr. M. R. Taylor sent a synopsis of some investigations made by himself in this field to the Surgeon-General's Office in 1864, and reported them to the American Medical Association in 1867. Dr. J. M. Da Costa reported the result of his investigations to the Sanitary Commission in 1867, and published it in the *American Journal of the Medical Sciences* in 1871. In the same year, 1871, Meyers, of the Coldstream Guards, wrote of the frequency of heart strain in the British army. In 1873 Fräntzel gave the results of his observations in the Franco-Prussian war. Since that time much attention has been given to the subject. One of the most earnest and careful investigators of this condition in civil life is Dr. Allbutt of Leeds, England.

A study of the literature of cardiac disease shows that the first attention given to this subject was due to the occurrence of sudden dilatation in army life. That sudden dilatation may occur has been recognized by Claude Bernard, Osler, Fothergill, Goodheart and many others. Dr. Gairdner suggests that if we place the finger over the apex where the impulse is felt most distinctly, then lean forward to a stooping position and hold the breath about one-half the expiratory interval, and continue this as long as possible, the impulse will gradually vanish as the distention of the right ventricle goes on until it is finally lost. Prof. Wyman makes the following report of experimental studies: He says: "I took a medium-sized dog, opened his chest after making tracheotomy, noted the action of the heart and the relative size of the two ventricles. Then I put the nozzle of a strong bellows into the trachea and distended the lungs with air. Under the pressure thus induced in the air-cells, the enveloping capillaries were elongated and the blood was dammed up in the pulmonary artery and the right side of the heart, distending the right ventricle to a remarkable degree. I found that an increase of pressure in the air-cells produced proportionate increase of pressure in the right ventricle. Subsequent repetitions on other animals showed that a peculiar pallor would appear in the tongue and membrane of the mouth when the right side of the heart was overdistended. Then in another trial I distended the pulmonary air-cells by placing a dog in a box while the air-pressure around the body inside the box was lowered three inches, as measured by barometer. Pallor of the tongue was again noted, and after the animal was taken from the box locomotion was performed with great difficulty; for days subsequently the exertion consequent upon a scramble for food would provoke dyspnea."

The suggestion of Dr. Gairdner and the experiment of Prof. Wyman point to the fact that dilatation of the right ventricle is the result of sudden interference with the circulation, or increase of blood-pressure. The condition, then, of heart strain originates in a forcible dilatation of the heart by blood-pressure from within. The damage, however, falls chiefly on the ventricles. This may occur suddenly, under great physical stress, or more slowly from causes less pronounced, but acting through a greater period of time. The right ventricle is most frequently affected. Dilatation of the left ventricle must be attributed to causes more remote, such as obstruction to the passage of blood through the arterioles of the general circulation, caused by muscular pressure, the elasticity of the larger arteries meanwhile easing the strain of the muscles appertaining to the heart. Shock is thereby lessened and the dilatation more gradual (Allbutt).

The effect of heart strain may best be understood by calling attention to the condition of the heart under normal circumstances. It is the function of the heart to carry on the circulation. Its work consists in moving a column of blood equal to about $^1/_{13}$ of the weight of the human body. Under normal conditions in a man weighing 156 pounds, this requires that the heart shall keep in motion a column of blood weighing in the neighborhood of twelve pounds. In each individual the heart is adjusted to the work to be done, so that an equilibrium may be maintained. This equilibrium may be disturbed to a degree and the natural recuperative power enables the heart to resume its normal condition; but if this disturbance continues by overwhelming efforts, or by continued effort in slighter degree, eventually the equilibrium may be destroyed and disease result. Muscular action increases the blood-pressure. Extraordinary effort, and even ordinary effort continued, may increase blood-pressure. If the heart is not overworked, that is, if only such effort is made as the heart is able to maintain without disturbing its equilibrium permanently, a degree of work is beneficial and will keep the system in a more healthful condition. But if extraordinary effort, either sudden or prolonged, is made, or if any other resistance to the peripheral circulation exists, as diseased arteries, or cirrhosis of the kidneys, lungs or liver, the blood-pressure is increased, the strain upon the heart is augmented, and the results of such strain must follow. These results are, in case of sudden and violent strain, engorgement of the right ventricle with blood and rapid dilatation. In the case of less pronounced blood-pressure dilatation will follow more slowly, but none the less surely.

The effect of heart strain, then, is seen in two ways, (1) by overwhelming disturbance, causing immediate faintness, possibly paralysis and death; (2) a more gradual dilatation from lighter and daily strain. When the shock does not terminate in the death of the individual at once the normal irritability of the heart is in a great measure lost. The heart muscles are in the condition of muscles in any other part of the body when the fibrils become unduly stretched and strained;

the rhythmic action becomes feeble, tremulous and imperfect. In the case of the heart the condition is one of profound asthenia; it is possible, even in this instance, for the effects of strain to be removed, and if the heart has the opportunity to rest under proper treatment it may recover its normal size in a short time, but its rhythm of action may be destroyed for weeks or months. If the strain is not sufficient to produce at once such destructive results, the changes, although less pronounced, may still be damaging. The functional disturbances of the organ are but expressions of the damage it has received. When the condition has existed until the second stage has been reached it is seen either as simple dilatation or dilatation with some hypertrophy. Later there may be dilatation with decided hypertrophy, or there may be hypertrophy without dilatation, the cavities retaining very nearly their normal size.

There are two periods of greatest danger; one is at night, during those hours when the periodical distress returns and when respiratory movements are most sluggish; the other is when, upon rising from a recumbent position, the column of blood in the upper part of the body is suddenly thrown back upon the enfeebled ventricles, thus at the same time diminishing the brain pressure.

When the arterial tension is already high it is increased relatively more by whatever tends to raise the blood-pressure. That mechanical stress or strain is an important element in the case of disease of the heart, no one of great experience can doubt. Most cases of certain diseases of the heart—hypertrophy, dilatation or valvular lesions—occur in those who have been subject to strain, such as hard manual labor, army life, athletic sports, football, bicycle-riding, high arterial pressure and the like. This is nothing less than should be expected in view of our knowledge of the circulation of the blood and the structure of the vascular system.

Reference has been made to the equilibrium of circulation. The circulation is oscillating and exhibits a certain variation of pressure under normal conditions, due in part to the natural elasticity of the vessels and in part to changes in muscular contraction. Injury is done to the heart whenever resistance is excessive, as muscular effort with a tight belt or casing surrounding the body, and even when slightly above normal for the individual, but continuous in rigid vessels, as in those of advancing years. Resistance to the heart's action and a degree of strain occur in cases of cirrhosis of the lungs, liver and kidneys, or mechanical effort continuously above what the elasticity of the vessels or the natural strength of the heart muscles can easily overcome. Dr. George Oliver asserts that observations with the pulse-pressure gauge have shown that when other indications are favorable the lower ranges of pressure are not only more salutary, but are very often compatible with the highest degree of health. The increase of blood-pressure caused by sudden and severe resistance is not characteristic of habitual muscle exercise and, indeed, later tends to reduce the mean arterial tension (Allbutt).

Persons who lead sedentary lives are more liable to heart strain than those whose lives are accustomed to habitual exercise. One who lifts a heavy weight occasionally is more liable to disease than one who does it continuously; but, if a continuous exertion is in excess of that to which the heart and arteries may easily adjust themselves, harm may result. Many of these cases occur in retired life. A man who has given up business and travels for pleasure often upon climbing a mountain or taking active exercise becomes faint or short of breath. The sudden compression of the blood-vessels by the muscles which are required to contract beyond their custom raises the blood-pressure sometimes to such a degree as to rupture a limb of the aortic valve. If no damage occurs at first, however, one may become accustomed to such exercise and rather improve under it. "Dr. Weber, during an ascent at the beginning of his holiday, stated the rise of pulse-rate to be 74 to 122, and after a week's active walking the rise was from 74 to 105."

According to Allbutt, dilatation of the right side of the heart is an early symptom of prolonged exertion, but sudden strains affect the aortic area. Other authors, as Barr and Oertel, affirm the same. Physiologists tell us that there is an initial rise of pressure in prolonged exertion, such as running, rowing, cycling, ball-playing and the like. The blood is not driven out of the heart at each contraction, hence slow dilatation occurs. The heart may adjust itself to the increased pressure. It is this condition which occurs in what is called getting the second breath, or "second wind." Accumulation of waste products occurring in the blood in cases of severe exercise may have some effect in producing stress of heart directly or indirectly (Allbutt). The physician will often suffer from such condition. Called suddenly in the night or at other times, in emergency cases, he frequently runs to the patient or to a train; when he reaches the spot he is profusely perspiring, short of breath, almost or quite faint, perhaps sick at the stomach; the face is cold; pulse rapid, small, of low pressure; examination will probably show an increase of cardiac dulness; the cardiac area is enlarged. If the patient is not too far along in years the dulness subsides after rest. If he is past middle life the pulse may become irregular and intermittent, and albuminuria may follow in the milder cases. In more acute cases pain and constriction are felt in the region of the heart, rarely in the arms. The pain may sometimes extend as far as the second interspace. There may be dyspnea, yawning, exhaustion, cold sweat on the forehead; the pulse may be irregular in force and rate and intermittent, the right ventricle enlarged. When blood-vessels are rigid, as in the aged, the danger is greater.

It was formerly supposed that heart strain

was confined to the profession of arms. The compression of belts and accoutrements seems to interfere with the natural elasticity and movement of the heart in its function of expanding to relieve the increase of blood pressure under strain, and it may precipitate trouble under physical efforts which the patient might perform ordinarily with ease. When at rest he feels fairly well. There is no distress, no throbbing in the chest. As soon as he puts on his accoutrements and begins drill everything is changed. The heart throbs more or less violently. A feeling of oppression with a difficulty of breathing is experienced, and a sensation of weakness, sickness or dizziness follows, and he may be compelled to fall out of the ranks. I saw such cases during my own military experience in the Civil War, but I was not then a physician and was unable to profit by that experience. The sensation, however, I understand, for I was one of the victims of the condition. We had been marching for some hours, and just before reaching camp we were urged to a more rapid step. As we ascended a hill I was made conscious that something was wrong; the heart began to beat hard, I grew faint, sick, dizzy and fell at the side of the road. I lost consciousness only a moment, but was not fit for duty until the next morning. At first the condition is only functional, the soldier being able to resume his duties after a brief rest. It is fortunate if the strain is not brought on again. I was soon transferred to a position where most of my duties were performed on horseback, and my heart trouble ended.

Where the duties remain hard or care is not exercised the symptoms remain and the conditions grow worse. In acute cases the symptoms are almost uniformly described as, first, a flush of the face, particularly the cheeks, chin, nose and ears, and deepened color of the lips; the veins of the neck become turgid and the respiratory movements are limited to the upper portion of the thorax; very soon respiration becomes labored, breathing short; there is profuse sweating, a deathly pallor and great weakness rapidly succeed, and, unless caught, the man falls to the ground.

My observations of heart strain and its results have been confined chiefly to athletes, baseball and football players, cyclists and soldiers of the Civil War, Spanish-American and Philippine Wars, and soldiers from the regular army. I have seen a few cases among boys, laboring men and travelers. The milder or slower form, resulting from slower processes, is very common among laborers, porters, hod-carriers and others engaged in employment where sudden and powerful effort is occasionally required, or prolonged effort (though of less pronounced character) is sustained.

One of the most marked cases of sudden heart strain occurring in my practice was the following, which occurred five years ago. Mr. A., proprietor of a livery stable, directed his men one day to lift a heavy wagon and move it to one side. The efforts were not satisfactory, and he impulsively took hold of the load and lifted beyond his strength. He was seized with faintness and fell to the ground. I was summoned at once and attended him at his home two blocks away, where he had been carried. I found that the first symptoms were those of acute heart strain, but there were in addition those of ruptured valve. He had great pain and difficulty in breathing; the heart action was slow and irregular; the valvular flapping sound at the aortic opening pointed to rupture. He informed me that he heard "something snap" in the region of the heart when he lifted the wagon. The cardiac area of dulness was large, but gradually subsided to smaller dimensions, as the patient recovered. The symptoms gradually declined, and in a few days he was able to resume the lighter duties of his occupation, but it was some weeks before the sounds and the condition of the heart returned to their apparent former status. As the patient had a valvular murmur prior to the accident it was not possible to determine how much permanent damage resulted from the strain. Dilatation, however, still exists, and is likely to become more troublesome as life advances.

There are many of those cases among boys and young men given to hard exertion in games. One such I mention as typical of many. Last fall I attended a young man who had overdone a great many times. I saw him once after a hard run. At first the face was flushed, the body covered with red and whitish areas; the heart was beating violently, and the breathing was difficult; blood-pressure was low; the cardiac area increased; the right ventricle dilated. The patient grew faint, became pale, slight nausea came on, but after a few minutes recovery rapidly succeeded. I have seen him in three of these paroxysms. The heart is not permanently impaired, and he may remain well, as he has promised to forego such hard exercise.

Allbutt reports the following case: "A man of letters, whose constitution had been shaken by profuse hemorrhage in early life, took to the bicycle in middle age, and often rode hard and far. He complained to me that at times he felt some discomfort from it. On careful examination I found no sign of disorder, but I begged him to end his next hard ride at my house. He did so, and I then found his heart irregular and intermittent, the arterial pressure low, and the right ventricle dilated. Fortunately, on his next visit he was well again, but repentant."

Such paroxysms in the middle-aged pass off more slowly, and with greater difficulty; in fact, the damage is more likely to persist in proportion to the patient's years. The pulse may remain irregular and feeble for a long time, and the breathing become embarrassed by the least effort.

In a series of examinations of some 700 ex-soldiers I have been interested in observing the large number suffering from some form of cardiac disease, most of which can be explained by reference to heart strain. These morbid conditions may frequently be observed in those who

were in the Spanish-American War; already some of them are showing signs of hypertrophy, dilatation, and excessive cardiac irritability. We are assured by surgeons of the British army that high temperature increases the liability to heart strain. With this in view I have thought that the sudden transfer of our troops from Northern soil to a hot and depressing climate has had something to do with the frequent occurrence of this condition amongst those who served in Cuba during the late war. The same observations may apply to those serving in the Philippines. Many of these soldiers were clerks or office men unaccustomed to hard work or heavy strains. The digging of trenches or going on forced marches with their tight belts and heavy accoutrements under the rays of the hot Southern sun suddenly overcame many of them, and in others initiated troubles which will finally drag them to their graves. What these troubles may be is illustrated in the cases of the pensioners of the Civil War. The greater number of these veterans, perhaps, are suffering from some form of heart lesion due to overstrain of the organ caused by the duties of their army experience. These conditions to-day are chiefly dilatation with or without hypertrophy, and sometimes valvular lesions; rigidity of the arteries is a frequent complication and one of fatal significance. If compensation has not been ruptured, if hypertrophy is still maintained in sufficient degree to keep the circulation in equilibrium, and if the arteries are in a fairly healthy condition, life may be prolonged for many years. If, however, equilibrium is not sustained, if dilatation is gaining and hypertrophy is losing, if compensation is failing, breathing becoming more difficult and exercise a task, dropsies come on and progress toward the grave is more or less rapid.

The study of these cases is interesting. Among pensioners all varieties and stages of the affection exist. Often all the distress is located in the stomach, a slight indigestion, and all the general appearance and bearing of the patient is such as to lead one to suspect gastric or intestinal disturbance or engorgement of the liver or spleen, without cardiac complications. He may not know that he has heart trouble. When asked about the short breathing he says that it came on gradually. Persistent inquiry, however, will often elicit the statement that at some time an accident occurred, or an effort was made, which will point to the origin of the ailment. Often, again, he will indicate the time clearly, but stating that faintness came on after drill, a march or exercise, but soon passed off. Sometimes there is vertigo and, perhaps, distress in the chest, particularly at night, and this is often accompanied by a smothering sensation, dyspnea.

The study of the pulse is interesting and instructive, but the sphygmographic tracings are not always satisfactory. In the first stage the pulse is weak. In the second it may be full and frequent and hastened by exercise: it is irregular or variable or jerky, intermittent and generally dicrotic. If the strain has been felt on the right side of the heart, chiefly, little is indicated by the pulse, except cardiac asthenia. In these patients we often see tremulous movements in the costal margins, or in the sixth or seventh intercostal spaces, which are easily felt by palpation. They are likely to be present in dilatation of the right ventricle, while they may be present in dilatation of the left.

Auscultation in the first stage is not always satisfactory, no signs being indicated except those of asthenia. In this stage there are no valvular lesions, no bruits nor murmurs, except in severe cases where a limb of a valve is ruptured. In the ordinary cases these signs are absent. It is often just as difficult to get a tracing of the radial pulse. It is only after the heart has passed beyond this stage that evidence of organic mischief is present. The systole then becomes very short. The heart contraction is reduced to half the usual time, the time between the first and second sounds is lessened, but a prolongation of the diastolic interval may be observed. The rhythmic movements may vary from 45 a minute in the recumbent position to 150 in the standing position or during moderate exercise.

Over the region where the tremulous movements are seen in later cases there will be heard a loud, rough, systolic sound of low pitch. If compared with the normal ventricular sounds of the left side, the difference may range anywhere from a half to a full tone in the diatonic scale. As a rule, it is heard loudest between half an inch of the left of the costal margin opposite and a little below its junction with the sternum; and again very distinctly anywhere on a horizontal line extending from, and to the right of, the apex (Taylor).

In cases of recovery where the cavity of the right ventricle has almost reached its normal size, this rough sound gradually passes away, so that it may not be observed until the cardiac movements have been extended by exercise, then the pitch will be higher. Should dilatation remain with or without hypertrophy, the rough sound retains its low pitch. If the hypertrophy diminishes the size of the cavity to nearly its normal state, the pitch becomes so nearly like that of the opposite side that it is no longer distinctive. Occasionally pulmonary accentuation is present, especially if the cardiac lesion originated in respiratory trouble. In such conditions of the heart there is more or less venous stasis, circulation in the extremities is feeble, hands and feet may be cold and the color, disappearing under pressure, returns slowly. I have lately seen a case in which there was such general turgescence of the veins of the chest and abdomen that there was a red blush over the entire surface, leaving a white mark upon stroke similar to that characteristic of certain cases of exanthematous rash. In such cases the lips will range in color from a cherry red to a livid hue.

One of the most interesting cases among ex-soldiers that I have examined is the following: During the Civil War the patient had typhoid

fever of medium severity. After convalescence and returning to his company, the command was sent upon a long march. He was overcome by the exertion and heat, became faint and exhausted and fell out of the ranks. He was carried in an ambulance to the camp and recovered in a few hours. Several times afterward he had a similar experience, and always since has had more or less trouble with his heart. At the present time the cardiac area is increased about 20 per cent. There is mitral, tricuspid, and aortic regurgitation accompanied by hypertrophic dilatation. Tremor of the chest-wall involves the entire thorax and extends throughout the body, the pulse thrill being especially observed in the arms. A confusion of sounds exists, a rushing, rasping, blowing over the entire area of the heart, especially marked over the right ventricle, over the apex, and at the right and left second interspaces. It is difficult to separate the sounds. The pulse is visible on both radial and ulnar sides of the wrist. The radial pulse is variable, full, vanishing, irregular, intermittent, with a peculiar tracing. The up stroke or ascent of the sphygmogram is quick and nearly vertical. The apex is a plateau. The down-stroke is characterized by a vibratile motion, but it is unbroken by the recoil or dicrotic wave. It is the sphygmogram of high tension, aortic, and mitral regurgitation. It seems strange that one in such a condition can engage in the ordinary duties of life, yet this pensioner is able to move about at will and does light office work, but he is unable to perform any manual labor. He suffers from frequent attacks of dizziness. Fortunately, compensation has not failed.

Treatment.—The treatment should be prophylactic, hygienic, dietetic and medicinal. Prophylactic treatment in civil life would require elimination of corsets and belts from ordinary dress; a quiet, well-regulated life, avoiding overexertion or any exercise that would produce a profound impression upon the heart. In military life it requires such an adjustment of accoutrements and exercise as will prevent overwhelming the heart in its efforts to carry on the circulation. The proper advice to such persons is to leave the service.

Hygienic treatment involves a well-regulated exercise, fresh air and sunshine, a well-ordered life and avoidance of excesses in any direction, systematic bathing of such temperature and character as will not produce shock, regular meals and sufficient sleep, the avoidance of all dissipation.

Dietetic treatment is particularly needful in advanced cases. All forms of food which have a tendency to the production of gas in the stomach or intestines, and all classes of food which produce digestive disturbances of any kind should be prohibited. The interval between meals should be of sufficient length to permit the complete digestion of one meal before another is taken. In mild and initial cases no change in the diet may be required. Where the work of the heart is excessive, liquids should be limited. Even a small amount of liquid beyond the necessities of the system may work damage by overtaxing the heart.

If blood-pressure is low, liquids should be administered to lessen resistance and increase elimination. Hence, the condition of the pulse tension, the force of the heart's action, and the quantity of urine will serve as guides to the amount of liquid required. Hot water acts as a stimulant in cases of cardiac diseases resulting from strain, and not only washes out the stomach after digestion, but strengthens a flagging heart.

In cardiac asthenia when dilatation is present a dry diet is indicated. It lessens the work of the heart. If the kidney is not involved a nitrogenous diet should be prescribed, as milk, the pulses, eggs and meat, gluten bread, almond meal, etc. If the disease is not of a severe type, other vegetables, such as onions, asparagus, lettuce and tomatoes may be allowed. Supper should be the lightest meal of the day. If patients are thirsty when on a dry diet, hot water may be taken between meals. Sometimes milk and lime-water, lemon-water, or a weak solution of phosphoric acid, will afford relief and may be given. Toast, nut-foods, nuts and fruits often act well. Like dry foods they should be thoroughly masticated. If compensation is failing and digestion is disturbed, the chief reliance is in liquid nourishment. The feedings should be small in amount and frequently repeated. Rest in bed is essential. Sudden dilatation requires rest in bed and a milk diet. Hypertrophy may require rest in bed and a non-stimulating diet. Well-cooked fruits may be given. The bowels must be kept open. If hypertrophic congestion of the liver occurs, some depletion may be required and a diet of milk or whey and soda and lime-water administered.

Before medicinal treatment is begun the cause should be removed if possible. In the first stages little, if anything, more than such management as has already been suggested will be required. In cases, however, where asthenia is present, digitalis and strychnine are the most important remedies; the addition of tonics will restore the tone of the heart and reduce its rhythmic activity. The duration of the treatment must be determined by the condition of the individual case. It will depend, somewhat, upon how the organ responds to the treatment; but so long as dilatation exists they cannot safely be stopped. If for any reason, however, these agents do not act well, some substitute for them must be found. There are two substitutes for digitalis which may be used alternately with that remedy, or in place of it, as circumstances may demand; these remedies are convallaria, strophanthus, and in some cases caffeine. Sometimes it may be found necessary to substitute nux vomica and other tonics for strychnine, but I have found that in most cases strychnine may be given, though occasionally small doses may be required. For hypertrophic overaction aconite is often useful, but it should be used with great caution. Gelsemium and aconite are sometimes required as cardiac sedatives. For distress at night, belladonna, hyoscyamus and can-

nabis indica are valuable remedies. Occasionally bromide of potassium or bromide of sodium and codeine may be required, though usually it is better not to use these preparations nor opium. Tonics and digestants may be of service in some cases. The treatment is that usually required in such cardiac conditions. Complications may necessitate a modification of treatment.

ON THE ACTION OF DIGITALIS.

BY ARTHUR R. CUSHNY,
OF ANN ARBOR, MICH.;
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS IN THE UNIVERSITY OF MICHIGAN.

AT THE end of the eighteenth century two important innovations were introduced into medicine by physicians practising in two neighboring counties of the west of England, the digitalis treatment of dropsy by Withering of Birmingham in 1785, and vaccination by Jenner of Gloucester in 1798. The sponsors of these methods derived their ideas from the same source, the popular medicine of the locality, and each worked in silence on his topic for many years before venturing to lay it before the medical profession.

The importance of Jenner's discovery has given his name a world-wide fame, but is it just that that of Withering should be known only to a few students? In his treatise on the subject he states that digitalis had been used by himself and his friends for ten years and gives the histories of over two hundred cases. He failed to recognize that digitalis acts chiefly on the heart, but differentiated between true dropsy and what appear to have been cases of ovarian cyst and states that in the latter digitalis produces little or no amelioration. After the appearance of Withering's paper, digitalis seems to have attained immediate popularity, though its position was afterward endangered by use in many forms of disease in which it could have been of no benefit. In 1830 it was generally recognized that its chief usefulness lay in the sphere of cardiac disease and soon afterward the first experiments were made on animals in order to ascertain its action on the circulation (Blake, 1839). A more serious attempt to elucidate its action was begun by Traube in 1851, and since then it has formed the subject of a large number of investigations.[1] Of late years more accurate methods of investigation than were at the disposal of the earlier workers have thrown much light on the action of digitalis; but before these are considered it may be well to discuss what are the active principles of the drug. Schmiedeberg in 1882 found three bodies in digitalis which acted in the same way on the heart and which he named *digitoxin, digitalin* and *digitalcin.* These were accompanied by other inactive bodies, the chief of which he named *digitonin.* More recently Kiliani has confirmed Schmiedeberg's findings and added another glucoside, *digitophyllin,* which resembles digitoxin in many features. All of these he showed to belong to the group of glucosides, and all of them are contained in the ordinary preparations of digitalis.

For nearly forty years after Traube's first experiments the only method employed in the examination of the effects of digitalis on mammals was the registration of the blood-pressure by means of the mercury manometer. This however does not permit a sufficient analysis of the changes in the heart; and although it was supplemented by direct examination of the frog's heart and by the registration of its movements under digitalis, it was felt that no direct inferences could be drawn as to the changes induced in the human heart. As a matter of fact, the reaction of the cardiac muscles in the frog under digitalis differs in some essential features from that of the mammal, and I shall therefore pass over the results of these experiments. The experiments performed on mammals with quantities of digitalis equivalent to those used in therapeutics showed two chief features, (1) the slowing of the pulse, (2) the rise in the blood-pressure. The slowed pulse is due to increased activity of the cardiac inhibitory apparatus, chiefly of the inhibitory center in the medulla oblongata. The increased blood-pressure is due in part to an increase in the amount of blood expelled by the heart, in part to contraction of the peripheral vessels, which increases the resistance to the current of blood from the larger arteries to the capillaries. It was further shown that the pulmonary vessels are much less affected than the systemic arteries; in fact, it may be questioned whether digitalis induces any contraction of the pulmonary arterioles.

During the last ten years, efforts have been made to obtain a deeper insight into the changes in the heart under digitalis, and it is gratifying to find that the most diverse methods of examination have given results which are in complete accord as regards all important features. These experiments vindicate for digitalis and its allies an action on the heart which is altogether different from that obtained by means of any other drug used in therapeutics. The slow pulse and the increase in blood-pressure which were observed by the manometric experiments are, on the other hand, induced by many other drugs, such as strychnine and often caffeine. The administration of therapeutic doses of digitalis to animals was found to be followed by slowing of the heart, an increase in the strength of its contractions and an increase in the dilatation. The slowness of the pulse is due to the heart's spending a longer time in rest between the contractions, or, as it is generally stated, to a prolongation of the diastolic pause. This slow pulse is not due to any direct action on the cardiac muscle fibers, for it disappears when the inhibitory mechanism is paralyzed by the injection of atropine. It proves, as has been already stated, to be due for the most part to stimulation of the inhibitory center in the medulla oblongata.

[1] For the bibliography of these see a paper by the author in the Jour. of Exp. Med., II., p. 233, 1897.

The increase in the dilatation of the heart, that is, of the relaxation of the muscle fibers, leads to the heart attaining a larger size in diastole than before the drug was administered; the heart therefore allows more blood to enter its cavities than before. This feature is less constant than are the others, and in my experiments it appeared to be more marked in hearts that were normal to begin with than in those that were already dilated before the drug was injected. The increased dilatation, like the slowing of the beat, proved to be due to inhibitory action and not to any direct action on the cardiac muscle. When the inhibition was removed by atropine, the heart resumed its normal rate of beat, or a faster one, and the relaxation of the muscles was the same as, or less than, that before the injection. The only marked feature that remained was the increase in the strength of contraction, which has thus a different origin from the slowing of the heart and increased dilatation, and which must in fact be referred to a change effected in the cardiac muscle itself. This increase in the strength of contraction naturally resulted in the heart attaining a smaller size at the end of systole than before the drug was administered; in other words, there was less blood remaining in the ventricle at the end of systole. It is now generally recognized that the ventricle does not empty itself completely at each stroke; there is always a smaller or larger amount of blood remaining over after the contraction, and before the inflow from the auricle begins. This action of digitalis is not confined to the ventricle, but extends to the auricle, and both right and left hearts undergo the same changes in rate, strength and dilatation. Roy and Adami pointed out, before my experiments began, that the papillary muscles are also involved and contract more strongly than before; in fact in some of their work the changes in the papillary muscles were much more marked than those in the ventricular walls proper. The greater strength of the contraction of the walls naturally leads to an augmented pressure in the interior, which has been demonstrated experimentally by Kaufmann, Rolleston and others.

The heart may be regarded as a complicated pump and its state of efficiency may be measured in the same way as that of a mechanical pump by the discharge per minute. Now, the experiments just detailed showed that the ventricle contained more blood at the beginning of its contraction and less at the end under digitalis than in normal conditions. Each stroke of the pump thus expelled more fluid than before; but there were fewer strokes per minute and it thus appeared possible that, although the contractions were stronger, the actual efficiency as measured by the output per minute might be lessened. As a matter of fact, further experimentation convinced me that after therapeutic doses the output per minute was larger than before, the slowness of the pulse proving insufficient to counterbalance the increase in the amount discharged by each contraction. The increase in the efficiency amounted to from twenty to thirty per cent. in normal animals. When larger quantities were given and poisoning was shown by the extreme slowness of the heart, the output fell to below that observed before the drug was administered.

Further advance in the methods of experimentation in the last few years has led several independent investigators[1] to examine the effects of digitalis on the mammalian heart when isolated wholly or partially from the body. These experiments permit only the direct action on the cardiac muscle, for the inhibitory center is destroyed and the slowing and increased dilatation are therefore entirely lost. The results confirm in the most satisfactory way those which I have described as occurring in an animal with its inhibitory mechanism put out of action. The contraction of the heart is stronger, the pressure in its interior is higher and the amount expelled at each beat is larger.

Do these changes observed in the hearts of the lower mammals suffice to explain the therapeutic effects of digitalis? The most general statement of the conditions in which digitalis proves of value is a displacement of the blood. Instead of being distributed in the arteries and veins in the normal proportions, it is lodged in larger quantities in the veins, while the arteries are only partially filled and the pressure in their interior is low. To return to the analogy of the pump, the piston refuses to rise sufficiently and the water remains in the well. In order to improve the condition, the efficiency of the pump must be improved; that is, the amount of blood discharged must be augmented. And, as we have seen, this is the effect of the cardiac action of digitalis. The accumulation of the blood on the venous side of the circulation leads to starvation of the tissues of the body, manifested by degeneration in such organs as the kidney and liver and in the vascular walls, which leads to dropsy and edema. Among the organs involved in the malnutrition is the heart itself, so that a vicious circle is formed, the inefficiency of the heart leading to malnutrition and this in turn lessening the strength of the heart and increasing the inefficiency. In such a case the heart muscle becomes flabby and the cavities are dilated; the contractions are often frequent but feeble, and but little blood is expelled by each beat. The primary cause of the condition is often disease of the valves and consequent regurgitation, but even when these are sound they become involved in the general disorder; for the papillary muscles and the muscular base of the valves partake in the prevailing relaxation of the cardiac muscle and the valves are accordingly not supported against the pressure put on them in systole.

The effects of digitalis on the heart muscle are exactly those adapted to counteract this condition. The contraction is increased in strength and probably the dilatation is slightly increased in diastole, although this is much less marked in

[1] Gottlieb. Verhandlungen des XIX. Congresses für inn. Med. zu Berlin, 1901, p. 25.

the dilated heart than in a normal one. The increased contraction augments the output of the heart and raises the pressure in the arteries, thus accelerating the flow through the capillaries. The increasing pressure in the veins promotes the return of the blood to the heart and lungs, whence it again returns to the arteries. The quickened circulation supplies a more adequate supply of food and oxygen and improves the nutrition of the vessels and organs and, chief among these, of the heart itself, which becomes equal to its task of pumping the blood from the venous to the arterial side. In many cases, however, the heart is permanently injured, as when a valve is shrunken by cicatricial tissue. Here the work required is far in excess of that demanded of the normal heart, for part of the energy expended in contraction is wasted in driving the blood backward instead of forward. In such a case the heart muscle has a special burden to carry in order to maintain the equilibrium, and, as in the case of other muscles subjected to a continual strain, it increases in bulk. The hypertrophy of a muscle can occur only when it is put in the most favorable conditions of nutrition and the hypertrophy of the heart is induced not through any direct stimulation of the growth of the muscle by digitalis, but by its nutrition being improved by the changes in the circulation, which are sufficiently explained by the increased contraction of the muscle fibers. Another explanation of the hypertrophy is based upon the inhibitory stimulation; the slowing of the heart is said to allow the organ more time for rest and reconstruction. But this seems contrary to experience in the hypertrophy of other muscles, for the blacksmith's arm is not increased in size by his giving it rest and the hardness of an athlete's muscles is only maintained by constant training. Again, it has been suggested that the inhibitory fibers are really the trophic nerves of the heart, and that the increased activity of this mechanism is sufficient to explain the hypertrophy. But apart from the doubt which may reasonably be entertained regarding any explanation based upon trophic nerves, the increased inhibitory activity is not sufficient to explain the phenomenon; for other drugs resemble digitalis in stimulating the inhibitory apparatus, while no hypertrophy results from their use. I need only cite the example of aconite, which increases the inhibition in exactly the same way as digitalis, but has no effect on the cardiac muscle in therapeutic doses. Amongst the many virtues credited to aconite, I believe hypertrophy of the heart has not been claimed hitherto, but if the hypertrophy under digitalis is due to inhibition, then aconite ought to be classed as a substitute for it.

One of the most marked features of the therapeutic action of digitalis is the slowing of the pulse. This is certainly due in large part to the stimulation of the inhibitory function and in those cases in which the frequency of the pulse is a marked symptom the inhibition may be a useful adjunct to the more essential action on the cardiac muscle. But it must be added that the slower beat is not uniformly a benefit, for the chief object of the administration of digitalis is to increase the output of the heart, and the infrequency of the contractions may sometimes almost counterbalance the greater discharge by each. The acceleration of the pulse which is so often a feature of dilatation and malnutrition is probably a manifestation of irritability of the excitomotor part of the heart. An insufficient supply of nutrition is often the cause of increased activity in other organs and the heart may well be excited to frequent contraction by the general stasis of the blood. The return to the normal rate induced in many cases by rest, when fewer claims are made on the heart, and the continuance of the normal pulse after digitalis has been discarded certainly suggest that, like the dilatation of the cavities, the rapid heart-rate in cases of inefficiency is due in large part to malnutrition. So that, although it is practically certain that the slower pulse observed when those cases are treated with digitalis is primarily due to the inhibitory stimulation, the improved nutrition of the heart must also favor a return to the normal.

In many instances of digitalis treatment, a remarkable improvement takes place in the regularity of the pulse. This has also been credited to the inhibitory stimulation, and I am not prepared to deny that this may share in the effect. But here, again, the direct cardiac action in increasing the food and oxygen supply may play a more important rôle than has generally been recognized. The most extreme form of irregularity of the heart is that known to physiologists as *delirium cordis*, which, unlike the delirium of the clinicians, is immediately fatal. In several cases Gottlieb observed this in excised mammalian hearts and was able to arrest it by digitalis. In these experiments there could be no question of inhibitory action, for the heart was severed from its nervous connections, so that the direct cardiac action alone could come into play. The nutrition was also unaffected, for the blood was not driven through the coronary arteries by the heart, but by mechanical pressure which remained constant through the experiment. The improvement must thus have been due to some unknown change in the cardiac muscle induced by digitalis. But little is known as to the cause of clinical irregularity, although some contributions to our knowledge made in the last few years indicate that it may be due either to excessive irritability of the auricle and ventricle or to the failure of these to respond to impulses emitted by the excitomotor apparatus or to failure of the last to send out a contraction impulse. Whether these different forms of irregularity are equally amenable to digitalis can be decided only by the comparison of a large number of pulse tracings before and after the administration of the remedy.

The third point at which digitalis affects the circulation is the muscular coat of the arterioles, which contract and tend to keep the blood on the arterial side instead of allowing its accumula-

tion in the great veins. This may undoubtedly aid the action on the heart in cases of cardiac inefficiency and may perhaps justify the persistent adherence of the profession to digitalis in these cases in spite of the claims of strophanthus, which is practically devoid of this vascular action. In cases in which the effects on the heart are to be elicited with as little increase in the arterial tension as is possible, strophanthus is to be preferred, however. Or, digitalis may be given with a vasodilator such as nitroglycerin. When the latter is employed, Marshall[1] advises that the first dose of digitalis precede that of nitroglycerin by several hours, as the latter acts much more rapidly and may induce a considerable fall in blood-pressure before the cardiac action of digitalis has commenced.

Digitalis is not used so frequently now as formerly in cases of internal hemorrhage, but a few lines may be devoted to this subject. The ground for this application was the contraction of the peripheral arteries, which, it was supposed, would narrow the orifice and lessen the escape of blood. But more blood is expelled from the heart than before, and more must escape through the vessels, so that, even though the ruptured vessel be narrowed, no corresponding diminution of the hemorrhage is to be anticipated.

BACTERIOLOGICAL DIAGNOSIS OF TYPHOID FEVER.

BY HENRY A. HIGLEY, M.D.,
OF BROOKLYN, N. Y.

The methods available in the bacteriological laboratory for the establishment of the existence of any disease produced by a given micro-organism are three in number: (1) The isolation and identification of the micro-organism producing the disease; here we receive the microbe from the body of the diseased person; we isolate; we grow it upon our artificial media and subject it to the tests which shall establish its identity; (2) the application of certain staining reactions to the micro-organisms received from the diseased persons, which reactions are peculiar to these micro-organisms and shall differentiate them from all other micro-organisms; (3) the effect or reaction produced by certain body fluids of persons suffering from bacterial diseases, when these fluids in certain dilution are brought into contact with micro-organisms of the same species with which the person is infected, which micro-organisms have been artificially cultivated in the laboratory. Such a method is the Widal reaction.

It is a self-evident fact that of these three methods the first is by far the most positive and absolute, because here we take the micro-organism from the body of the diseased person; we cultivate it upon artificial media and subject it to a number of tests, the physical and chemical nature of which we in most cases clearly understand, in order to establish its identity. The chances, therefore, that we may make a mistake in regard to its identity are reduced to the very minimum and are not worth serious consideration. The second method comes next in value because of its simplicity, the ease with which it may be employed by the clinical practitioner, and its reasonable certainty. It can never, however, be considered as sure as the first method, because here we submit the organism to one kind of a test only, namely, a staining reaction. The chances, therefore, that we may make a mistake with regard to its identity are greater than in the first method, in which we employ several kinds of tests for this purpose. The third method is the most insecure of the three. This is so because we really understand very little from a scientific standpoint in regard to the ultimate factors which control these reactions. In the first place, we do not know what the substances are in these body fluids which give rise to these reactions. We say that there are such substances and we call them by certain names, but they have never been isolated; we know nothing of their ultimate chemical composition; we do not know how or whence they are produced nor the conditions, from a scientific standpoint, which limit their production on the one hand and their non-production on the other. Our entire knowledge in regard to their production is mere speculation derived from insufficient and often conflicting experimental data.

Let us now consider the application of these methods to the clinical diagnosis of typhoid fever. In this connection I purpose to invert the order in which they have been given and consider first the third method, namely, the Widal reaction, because it is the one about which I shall have the most to say and also because of its widespread use at the present time. Lest anyone should form a misconception in regard to my opinion of the value of the Widal reaction as a means for the diagnosis of typhoid fever, I want to say that I believe its value as such a means cannot be overestimated. It is nevertheless to be remembered that its true value, its great value, can only be fully appreciated when one takes into consideration the limits within which such value exists.

The Widal reaction, what is it? It is simply and solely a laboratory systemic symptom of typhoid infection. To be more explicit, it is the effect produced when the dried blood or blood-serum of a typhoid patient is brought into contact with artificially cultivated typhoid bacilli (I leave out of consideration here the fact that other substances, as well as various other body fluids of those sick with typhoid, will produce this same result). The effect thus produced is as follows: These typhoid bacilli, which exist singly in suspension in the artificial fluid media and possess motility, become, in a variable time, in greater or less number massed or clumped together and remain thus massed, losing their motility. The free organisms, those which do not mass together, if there are any, either entirely

[1] Jour. of Physiology, XXII., p. 1.

loose their motility or have it but little, if any, affected. I make this statement advisedly because it is a fact that there does not exist to-day in the minds of the best men a uniformity of opinion as to what really constitutes a Widal reaction of standard clinical value. The points of difference in the opinions of such men are as follows: (1) As to whether the free organisms, if there are any, need or need not lose their motility; (2) in regard to the degree of dilution of the blood or serum which must produce the reaction; (3) in regard to the time within which the reaction must be produced after the elements are brought together in the laboratory. There are those who tell us that in addition to the clumping the motility of all the free organisms must cease; that this result must be produced with at least a given dilution of the blood or serum, and that this must take place within a given time after the elements are brought together. On the other hand, there are those who hold that, in the very nature of things, one cannot lay down any hard and fast rules up to which this reaction must measure, in all cases, in order that it be of standard clinical value, but that there are certain limits within which the reaction may take place and yet be of standard value. These point out that the conditions in typhoid, both systemic and local, are due principally to two factors, (1) the degree of virulence of the infecting organism, and (2) the peculiar individuality and susceptibility of the infected person. These factors are, however, variable quantities. To suppose therefore that any condition, either systemic or local, must in all cases measure up to certain absolute standards in order to be of standard clinical value is illogical. In our present state of knowledge the latter view is certainly the one to be preferred.

A satisfactory conception of the clinical value of the Widal reaction, together with its correct application to individual cases, can only be obtained by a consideration of the vital factors which govern its production. These are five in number and may be considered under the following questions:

1. *What Are the Substances Which Produce These Reactions and Whence Do They Come?* The final answer to this question is very easy—we do not know. The latest and what I believe to be the best hypothesis in regard to them is as follows: These typhoid bacilli contain in their bodies, probably in their cell membranes, a peculiar albuminoid substance called the "agglutinating" or "agglutinable" substance. When these organisms enter into the human economy and the vital reaction is set up, the body by means of its cells, probably the leucocytes of the blood, produces a substance, perhaps in the nature of a ferment, called "agglutinine;" this substance, acting upon the peculiar albuminoid substance in the bodies of the organisms, produces a coagulation of the latter and causes the bacilli to clump or "agglutinate." The whole process then, is one of protection on the part of the body in answer to an existing infection. In regard to the ultimate chemical composition of these substances we know practically nothing. We do know, however, that they may be locked up with one or all of three constituents of the blood, (*a*) the fibrin or fibrinogen, (*b*) the serum-albumin, (*c*) the serum-globulin. When one or all of these substances, as the case may be, are removed from the blood, it loses its power to produce this phenomenon.

2. *When and Under What Conditions Are the Substances Produced and What Relation do They Bear to the Disease?* That is, (*a*) are they present early or late in the disease? (*b*) When once present do they remain present and for how long? (*c*) What relation do they bear to the immunity produced in the disease? (*d*) What relation do they bear to the virulency of the infecting bacilli and to the susceptibility of the infected individual?

a. They may be present either early or late or not until convalescence is established. Figures show that in the first week they are present in about 20 per cent. of cases; in the second week, in about 60 per cent.; in the third week, in about 80 per cent., and in the fourth week in about 90 per cent. From this the important fact follows that the demonstration of their absence on any given day proves absolutely nothing against a positive diagnosis of typhoid fever. This statement, however, needs a little qualification, which will be given later.

b. When once present they usually do remain present throughout the disease and on into convalescence, as a rule disappearing in the first weeks following recovery, but occasionally remaining for months and even years. It is perfectly possible for them to be present on any given day or succession of days and then to disappear suddenly never to return again. From these facts two important considerations follow, namely, the demonstration of their absence on any given day in a fever is not proof positive that they have not been earlier present, and it is necessary to ascertain whether or not the person has previously had typhoid in order accurately to interpret results.

c. The majority hold that they do not bear any relation to immunity, because they are often present in the early days of the disease when it is conceivable that any degree of immunity exists. There are those, among them Pfeiffer, who hold that they do bear a relation to immunity because they are present with greater frequency in the later days of the disease when some degree of immunity has been acquired. Exactly where the truth lies in this respect, it is at present impossible to say, but it does not seem probable that they are in any way related to immunity.

d. They are present in mild as well as in severe cases, in cases which recover as well as in fatal cases. The rule here is that the milder the case the less pronounced is the reaction, but there are many exceptions. Very many mild cases

give early and pronounced reactions and some severe cases give a delayed and feeble reaction or no reaction at all.

3. *What Are the Conditions, if Any, up to Which the Laboratory Organisms Employed in the Test Must Measure in Order that the Result Shall Be of Standard Clinical Value?* In regard to most of the points under this head we are to-day practically in accord. We believe that the organism should be in young culture, not over twenty-four hours old, and that it should be actively motile. Some favor ordinary nutrient bouillon as the culture medium to be employed for its growth while some prefer other media. None of the best men, so far as I know, hold that we should use very virulent micro-organisms, because there are certain substances present in non-typhoid blood which give with these markedly virulent organisms confusing reactions. There are those, however, who hold that we should use micro-organisms of a medium grade of virulence and others who claim that only greatly attenuated micro-organisms should be employed. The former tell us that if we use only greatly attenuated micro-organisms we elicit positive reactions in a greater percentage of non-typhoid cases than when we use micro-organisms of a medium grade of virulence. The latter claim that if we use only micro-organisms of a medium grade of virulence we fail to produce a positive reaction in a greater proportion of cases of genuine typhoid than when greater attenuated micro-organisms are employed; thus, the full clinical benefit of the reaction is lost. Exactly where the truth lies in this respect it is impossible with our present knowledge to say.

4. *Are the Agglutinating Substances Present in Atypical Cases of Typhoid with Equal Frequency as in Typical Cases?* We know that in cases of typhoid which come within the typical class these substances are present at some time during the disease in the vast majority of cases. Different sets of statistics vary all the way from 88 per cent. to 99 per cent. of such cases. The question here is *not,* What does the presence of these substances, in sufficient amount, mean in atypical cases? but the question is, Are they present with equal frequency in atypical and typical cases and so available for diagnostic purposes? I believe that before we can decide this question it is necesary that a considerable number of cases should be worked out along certain lines, as follows: We must show atypical cases of fever which give a positive Widal reaction in a high dilution and then either by isolating the typhoid bacillus during life or by following the case to the autopsy-table and there, by the pathological lesions or by isolating the typhoid bacillus, prove that we are dealing with typhoid infection. Literature contains comparatively few cases that have been so studied. It has been the custom in atypical cases of fever which persistently refuse to give a positive reaction to negative a diagnosis of typhoid. Whether we have been justified in so doing cannot be determined until more knowledge is obtained.

5. *Are Specific Agglutinating Substances Present in Conditions Other than Typhoid and in Normal Blood?* We know that they are. In other diseases the figures vary from 1½ per cent. to 19 per cent. The practical point, however, is that in these instances they are not present in anything like the amount in which they occur in typhoid infection, so that in order to produce a positive reaction it is necessary to use a very much lower dilution of the blood or serum. We thus produce a positive reaction in quite a percentage of other conditions when we use a 1 to 5 dilution, a less number when we use a 1 to 10 dilution, still less when we use a 1 to 15 dilution, and only very rarely when we use a 1 to 20 or 25 dilution.

In regard to the time within which the reaction must take place after the elements are brought together in the laboratory, we find that the views of the best men vary all the way from fifteen minutes to two hours. It is necessary in practice, however, to have some guide and it seems probable that thirty minutes is a safe and fair limit.

With respect to the technic of the reaction there are two points which deserve special mention.

1. *Making the Dilutions.*—Since the clinical value of this reaction is essentially one of dilution I hold that too much care cannot be taken in this respect. For this reason I personally discard the so-called dried blood method in which the degree of dilution is gauged by the shade of color produced when the dried blood and diluting fluid are brought together, one carrying in his mind's eye a different shade of color for each dilution; or the dilution is produced by adding to the drop of dried blood a certain number of drops of the diluting fluid and thoroughly mixing them together. I do not believe that with such a technic one can form any more than a very moderate opinion in regard to the degree of dilution with which he is working. This dried blood method has come into use chiefly because it was thought to be an easier clinical proposition than were the older methods of securing the serum by means of a blister or puncture. If, however, one will employ capillary tubes it will be found just as easy to collect the blood in these as it is to obtain it on a slide and let it dry. No more blood is required and the puncture does not need to be any deeper or more painful and in addition one has the satisfaction of knowing that he has the serum in a position to be used with great accuracy. In making the dilutions the most common practice is to use the looped needle, but in so doing we fall into inaccuracy. It is impossible to get off from the needle the same amount of fluid every time, so that one has a succession of drops of different sizes and the result is that the dilution is inaccurately made. By the use of the capillary pipette this error may be very largely obviated.

2. *The Avoidance of So-called Pseudo-Reactions.*—These are principally brought about by three causes: (*a*) When clumps of fibrin or for-

eign material present in the blood are brought into the presence of the micro-organisms, these attach themselves to such clumps, the appearance of an actual reaction being produced, when in reality only a pseudo-reaction has taken place. (*b*) Too many bacilli are often present in the microscopical field. They cannot move about with freedom and cause a confusing appearance. (*c*) In the bouillon culture there may be present bacilli attached together in masses; these when mixed with the serum and placed under the microscope lead us to suppose that a positive reaction has occurred. The first two of these sources of error may be practically entirely overcome if the technic with the capillary tube is employed. The chances of fibrin or foreign material being drawn up into such a tube are very few and experience shows that the number of organisms so entering is just about the number required. In regard to the third source of error, this may be very easily obviated if one will take a drop of the bouillon culture, examine it under the microscope and then, if it is found satisfactory, use this *same* drop to produce the reaction.

In considering the application of the Widal reaction to the diagnosis of typhoid fever, it is obvious that in any given case one of two results will be apparent, its absence or its presence.

1. *Its Absence.*—The absence of a positive reaction on any given day in a typical or atypical typhoid fever proves nothing against a positive diagnosis. If we can show by a sufficient number of observations that a positive reaction has never occurred, or that in the fourth or fifth week of the fever it is absent, we undoubtedly have a point of certain weight against a diagnosis of typhoid, but that such a result negatives a diagnosis of typhoid fever is absurd.

2. *Its Presence.*—We may have its presence in cases which are clinically typical or atypical of typhoid.

a. Typical Cases.—Its presence in typical cases (and by typical cases I do not mean cases which present all the typical symptoms of typhoid, but a sufficient number to be considered within the typical class) in a 1 to 10, 15 or 20 dilution probably throws enough weight on the side of typhoid fever to make a positive diagnosis justifiable.

b. Atypical Cases.—I believe that just so long as we know that there are conditions other than typhoid which give a positive reaction in a 1-10, 15, 20 or 25 dilution, we must show in atypical cases of fever a positive reaction with a dilution higher than these in order to justify a positive diagnosis of typhoid infection. If we are unable to do this and are only able to show a positive reaction in the low dilutions mentioned we must control the case by other laboratory factors in order positively to diagnose typhoid. Failing to do this we must say that a probability only of typhoid infection exists.

In regard to the second method available in the bacteriological laboratory for the establishment of the existence of any disease produced by a given micro-organism, namely, that of the staining reaction, this can be disposed of with respect to typhoid fever in one sentence. No stain has as yet been discovered which is able to differentiate the typhoid bacillus from other organisms.

We now come to the third method available for diagnostic purposes—the isolation and identification of the specific micro-organism. I do not propose to take up all the methods for isolating and identifying the typhoid bacillus. Some of these yield very good results, but others are not to be recommended because of the narrow limits within which they are applicable. I shall explain in detail only one method, the Hiss method, because of its wide range of application at all seasons of the year and because, when competently handled, it is second to none in its ability to differentiate the typhoid bacillus from all other organisms. Before considering this method it is necessary to consider briefly isolation methods in general. Isolation methods in general when applied to typhoid fever and particularly to typhoid fecal matter possess one great disadvantage. Typhoid bacilli when present in voided fecal matter remain alive only for a very short time, or if they do not perish they lose their original characteristics, so that they cannot be isolated by any method at present known. The length of time that they do remain alive or retain their original characteristics is very variable, depending no doubt upon the different nutrient conditions which surround them. This time varies in most cases from a few hours to a few days, probably nearer the former than the latter. This fact renders it necessary that fecal matter should be examined within a very short time after it has been voided by the patient and largely limits the use of all isolation methods in public laboratories where specimens are, of necessity, received under all conditions and where it is practically impossible to subject them to examination within a short time after they have been voided by the patient.

The Hiss method consists in the use of two media—one known as the "plating medium" and the other as the "tube medium." A tube of the "plating medium" is liquefied by heat and then cooled down to a temperature which will not injure the micro-organisms which are about to be introduced into it, but which still leaves the medium in a fluid state. The fecal matter, having been previously emulsified in sterile bouillon, is then introduced by means of a sterilized looped platinum needle into the fluid "plating medium" and by a twisting motion of tube equally distributed throughout it. Dilutions are then made from this tube into other tubes of the "plating medium," which has been previously fluidified by transferring a small portion from tube No. 1 into tube No. 2 and from tube No. 2 into tube No. 3. This is done in order that the organisms may be well separated, so that the colonies will not be too closely packed in the "plates" which are to be made. The contents

of each tube is then poured into a Petri dish which has been previously sterilized by heat. The medium is allowed to harden in these dishes, which are then placed in the incubator at 37.5° C. for sixteen to twenty-four hours. At the end of this time we find that the single organisms have been held in position as the medium hardened and have developed into colonies. There are, of course, many such colonies on any given plate. If typhoid bacilli are present they make their presence known in the formation of peculiar thread-forming colonies of a light-green color, while other organisms grow in non-thread-forming colonies. It is not claimed that this is always the case—that is to say, that typhoid bacilli never form non-thread-forming colonies and that other micro-organisms never form thread-forming colonies. If this were always the case, no second medium would be necessary for the complete isolation and identification of the typhoid bacillus. It is claimed, however, that in any given case a sufficient number of typhoid bacilli give rise to these thread-forming colonies, so that if these organisms are at all present they will be detected. To meet the contingency mentioned the "tube medium" is brought into play. These dishes are uncovered and placed upon the stage of the microscope; by means of a sterilized platinum needle a number of these thread-forming colonies are "fished" and transplanted into this "tube medium" by means of a "stab inoculation." These tubes after having been thus inoculated are incubated for sixteen to twenty-four hours. If the micro-organism which has been thus transplanted is a typhoid bacillus there occurs a diffuse cloudiness evenly distributed throughout the medium or a greater portion of it without the production of gas either free or evolved by stirring. If the micro-organism is not a typhoid bacillus it does not cause such a diffuse cloudiness and may or may not produce gas.

It is claimed that any micro-organism which responds characteristically to both of these tests is a typhoid bacillus and will respond to any test known for that organism. If any man thinks he has obtained results other than this I would like very much to see the organism with which he is working, for I believe that if such a result has apparently been obtained it is due to the fact that the media which has been employed has not been properly made. This leads me to the next point. The chief objection which has been raised to this method is that it is a very difficult one to pursue; that, in particular, the "plating medium" is a hard one to make. The reason that it is regarded as a difficult medium to make grows out of the fundamental conditions which exist in bacteriological laboratories to-day. It is a fact that there does not exist a uniformity of methods in different laboratories with respect to the manufacture of artificial culture media. To no one point does this apply with greater force than to the method employed for regulating the degree of acidity or alkalinity of such media, and, what is more important still, to the production of the normal acid and alkaline solutions by the means of which such a degree of reaction is produced. It is no wonder, then, that men working with different methods find difficulty in producing a medium, such as this, the usefulness of which largely depends upon the fact that its degree of acidity must be regulated within narrow limits.

It is also claimed that there are a few species of typhoid bacilli which fail to react to this method. If this is the case—and it has by no means been proven—statistics show that it is so seldom the case that it in no way invalidates the method as a means of diagnosis.

Now, what can we do with this method? Dr. Hiss' statistics show that from the sixth to the thirtieth day in typhoid fever it is possible to isolate the bacillus from the feces in about eighty per cent. of cases. My own experience, which is limited to sixteen cases, is much better than this for in only one did I fail; this was unquestionably a case of typhoid, as shown by the presence of a positive Widal reaction with a 1 to 50 dilution and a characteristic leucocyte-count. I do not hold, however, that it is as infallible a method as my statistics would show, for I believe that my results have been somewhat due to good luck in that the fecal matter in these cases contained a large number of typhoid bacilli. I want to state, however, that in my cases in all but three the tests were made within three hours after the feces had been voided by the patient. This speedy examination of feces after excretion by the patient I believe to be, in our present knowledge, an essential point in the carrying out of any isolation method.

There are two other laboratory factors available for the diagnosis of typhoid infection which deserve mention. These, although perhaps not strictly bacteriological in nature, are nevertheless too valuable to miss in this connection. We have known for a long time that the leucocyte-count in pure typhoid infection presents certain differences from that which occurs in other infective conditions. Dr. Thayer of Johns Hopkins University has recently taken up this subject and made a very extensive study of it. He shows that in pure typhoid infection, in addition to a hypoleucocytosis, the percentage relationships of the different classes of leucocytes is altered from that which occurs in health or other infective conditions. The polyneutrophilic leucocytes are markedly reduced in number, often falling as low as fifty per cent. The large mononuclears are increased in number, constituting from five to fifteen per cent. The lymphocytes and eosinophiles remain about normal. No abnormal leucocytes are present. A consideration of these facts shows that in the differential leucocyte-count we have a laboratory factor of vast importance in the diagnosis of typhoid infection.

The Ehrlich, or so-called diazo-reaction, I only mention here in order to condemn it as a means in the diagnosis of typhoid infection. It

occurs in altogether too many other conditions to be of any considerable value here. It may, however, be of slight use in connection with a slightly pronounced leucycyte-count or a positive Widal with a low dilution in atypical cases where a patient search for typhoid bacilli in feces and urine has been unsuccessful.

The practical question which now confronts us is, What aid is the laboratory able to render in the diagnosis of typhoid infection? In the consideration of this question I do not propose to outline the methods of procedure most suitable for employment in large public laboratories where work is often necessarily done under great disadvantages, but to indicate the most accurate procedures when put into operation under the most advantageous circumstances and in the most competent hands.

In clinical practice patients with typhoid fever present themselves for diagnosis at various times during the course of the disease. For practical purposes they may be divided into two classes according to the time in the course of the disease that they come under the observation of the practitioner: (1) Patients in the second, third and later weeks of the disease in whom the characteristic symptoms have not developed and where oftentimes the diagnosis must forever remain in doubt unless some aid is invoked other than clinical symptoms. (2) Patients in the first week of the disease in whom characteristic symptoms have not yet developed and where we seek to make an early and sure diagnosis.

In the first class of cases, except from the beginning of the fourth week on, I give preference to the Hiss isolation method. From the fourth week on I give preference to the Widal reaction. I give preference to the Hiss isolation method for three reasons: (*a*) Scientifically it is the best proposition and clinical statistics show that it is the surest proposition. No competent bacteriologist doubts for an instant that the isolation and identification of a given micro-organism received from the body of a diseased person is by far the surest and most absolute way to prove that the person is infected with that micro-organism. Clinical statistics show that we are more apt to isolate the typhoid bacillus from the feces in this class of cases than we are to get a positive Widal reaction. Let us see. Different authors vary slightly in regard to the statistics of the Widal reaction. A fair estimation, however, is as follows: In typhoid fever in the second week we get a positive reaction in about sixty per cent. of all cases; in the third week in about eighty per cent.; in the fourth and later weeks, in about ninety per cent. As previously stated, by the Hiss method the bacillus can be isolated from the feces in about eighty per cent. of all cases. In the second week, therefore, the very time that the vast majority of these cases come up for differential diagnosis, we have a leeway of twenty per cent. in favor of the Hiss method as the surest proposition. In the third week we have an even chance in addition to the fact that scientifically it is the better proposition. In the fourth and later weeks the Widal reaction has ten per cent. advantage and I believe that at this time the Widal is the preferable method. It may, however, be claimed that these comparisons have not been fairly made; that the facts do not show that it is possible to isolate typhoid bacilli from feces in eighty per cent. of cases in the second week, but that this result can be accomplished from the sixth to the thirtieth day. If we draw a comparison on this basis we see that the Widal reaction, giving positive results in sixty per cent. in the second week, eighty per cent. in the third week and ninety per cent. in the fourth and later weeks, gives an average of seventy-six and two-thirds per cent. in practically from the sixth to the thirtieth day. Hence, on this basis we have a leeway of three and two-thirds per cent. in favor of this isolation method, in addition to the fact that scientifically it is by far the better proposition.

b. Clinically it is the easier proposition. I do not know what the experience of other men is, but mine is that it is not always the easiest and simplest thing to get blood from a person sick with typhoid. Of course we can do it and do do it, but when we consider that in order to get out of a Widal reaction what there is to be got it is fairly probable that we shall have to take several blood specimens at various times it does not become the easiest proposition for the clinician to handle. Compare this with the very simple method of obtaining feces. These may be procured when voided without in any manner disturbing the patient and without his knowing that any special research is to be made.

c. From a laboratory standpoint this isolation method is the easier proposition. It takes actually less time to conduct this isolation test than it does to do a Widal as it should be done. The elapsed time, thirty-six hours, is quick enough for all practical purposes. Of course I speak here only in regard to the man who is thoroughly drilled and competent to handle the method. A positive result with the isolation method, of course, means a positive diagnosis of typhoid. Does a negative result negative a diagnosis of typhoid? By no means. In case of a negative result it is necessary to go back and control the case by other laboratory factors, such as the Widal reaction and the leucocyte-count. In this way I believe it is possible to say with great positiveness in this class of cases that a disease is or is not typhoid.

In the second class of cases, those in the first week of the disease in which the characteristic symptoms have not yet developed and we seek to make an early and sure diagnosis, it must be confessed that laboratory aid is of limited service. Isolation tests are useless and in our present knowledge a waste of time. The most valuable methods here are the Widal and leucocyte (differential) count. If we are fortunate enough

to secure positive results we have a diagnosis. It not we must wait until a later time.

Latterly much has been said in regard to the occurrence of typhoid bacilli in the urine during and subsequent to typhoid fever. While it is true that the bacilli are present in the urine in a fair proportion of cases of this disease, observation has shown that they do not appear in this location until the defervescence of the disease has begun. Very often they are not found until the temperature has practically returned to normal. These facts render the bacteriological examination of the urine of little value from a diagnostic standpoint, except in rare cases which are not seen until convalescence is nearly established.

During the last few years numerous endeavors have been made to obtain the specific bacilli from the blood of typhoid patients. In many quarters such attempts have met with marked success, the organisms having been found in from 70 to 83 per cent. of the cases examined. While this procedure as a diagnostic measure strongly appeals to the scientific observer, it is scarcely probable that it will be adopted by the clinician for routine employment, except perhaps in hospital work. For the proper carrying out of this method at least 5 c.c. of blood are necessary. The discomfiture to the patient in obtaining such an amount is a serious obstacle to the employment of this procedure in private practice. It seems certain that its use should be restricted to those cases in which all other methods of bacteriological diagnosis have been tried without avail.

In considering the bacteriological diagnosis of typhoid fever, as applied to individual cases of this disease, one idea should always be borne in mind. There is no one method by means of which a man can sit down in the laboratory and with ease and positiveness make a diagnosis for or against typhoid in all cases. It is only by bringing into play all the factors that the laboratory can control, by taking these and very carefully working them out, and then going back to the bedside of the patient and there carefully intertwining the results with the clinical picture of the case that a man can say in very many disputed cases that a disease is or is not typhoid fever.

MEDICAL PROGRESS.

NEUROLOGY AND PSYCHIATRY.

Rate of Vibration in Ankle Clonus.—It seems possible that some aid in the diagnosis of neurosclerotic conditions may have been rendered by the observations of J. A. MacWilliam (Brit. Med. Jour., Nov. 30, 1901), who, by a system of delicately-arranged tambours and an improved registering apparatus, has obtained much more accurate results than previous observers. Gowers says: "The movement is uniform, from six to nine contractions per minute." Horsley and Herringham observed a frequency of from four to ten. The tracings of MacWilliam in some cases look very much like dicrotic pulse waves; those taken of the quadriceps during a knee-jerk show three or four distinct vibrations of that muscle. These more searching records confirm the observations of Herringham, who noted the tendency to fusion in some tremors. It thus seems more than probable that in ankle clonus the foot movements show only half the real number of vibrations in the muscle, but unfortunately we have, as yet, no definite knowledge as to what relation the cord bears to the rate of vibration.

Treatment of Neurasthenia.—Since this condition results from nervous exhaustion and certain changes take place in the nerve-cells due to their activity, rest is the treatment which is specially indicated. H. C. Patterson (The Med. Times, Nov., 1901) believes that the Weir Mitchell rest-cure modified to suit individual cases is most effectual and that the details are all important. The diet is a difficult problem, but milk modified as koumyss or matzoon, or peptonized milk can usually be taken in small quantities; during the first two weeks the patient should not be allowed to take enough to entirely satisfy his hunger. Cautiously his diet should be increased by the addition of small slices of stale bread, adding, a little later, a small chop or steak in the middle of the day and a nicely boiled egg for breakfast. His diet is gradually built up till he eats three good-sized meals during the day. Drugs are of very little use unless indicated for some special symptom. Isolation and complete freedom from care are most necessary. Massage judiciously begun and electricity should be employed in nearly every case. The faradic current is used, first to the individual muscles, then to the whole body. It will take nearly forty minutes to go over the body systematically, and then a large sponge is applied to the nape of the neck and another to the soles of the feet, allowing the current to pass for twenty minutes. The standard for the success of the treatment is whether the color of the patient is becoming better and the flesh is becoming firmer and the weight increasing. After six or eight weeks, depending upon the severity of the case, the patient should be gradually gotten up again and sent to a quiet resort for a couple of weeks at least. It is well to remember that a rest of ten or twelve weeks is less likely to be followed by a relapse than one of shorter duration.

Action of Toxic Sera upon the Peripheral Nerves.—Certain auto-intoxications are accompanied at times by peripheral neurites. Similar nervous manifestations are also frequently observed during the course or subsequent to various infectious maladies as tuberculosis and diphtheria. In all cases the microscopical lesions have been found to be identical. Wallerian degeneration is habitually present. On account of the clinical and histological similarity of the neurites observed under these conditions it has been thought that, because in those of infectious origin bacterial toxins are responsible for the changes found in the nerve fibers, in auto-intoxications a like rôle is played by poisons, accumulated in the body, due to a functional derangement of the various organs. C. Dopter (Archiv. de Méd. Experimentale, Nov., 1901) by experimental means has conclusively proven this assumption. He finds that certain toxic sera (uremic, diabetic, cancerous, asystolitic and that of Addison's disease) when placed in contact with the peripheral nerves cause alterations in their elementary fibers. These lesions are identical with those caused by bacterial toxins, viz., peri-axilar segmentary necrosis and Wallerian degeneration. The intensity of these changes varies with the serum employed. Sera coming from various uremic, diabetic, etc., patients do not cause lesions of an equal degree of intensity. The serum from the same patient inoculated into different animals produces changes of unequal severity. In general it may be said, however, that the extent of the lesion depends upon the toxicity

of the serum employed. In analogy with these results it seems certain that the peripheral neurites observed in autotoxic conditions are due to retained toxic products in the blood which constantly impregnate the elementary fibers of the nerve trunks.

Nervous Insomnia.—In an interesting pamphlet, T. HEIM discusses the treatment of insomnia as it so commonly occurs in neurasthenia and hysteria. Like most other authors he decries the use of drugs, since they do not produce natural sleep but narcosis during which assimilation is reduced. Sometimes a glass of strong beer or porter will act well and rarely the use of bromides, bromidia, sulfonal or trional may be necessary. The latter two are, however, capable of setting up toxic symptoms, and hedonal and dormiol are preferable. The chief mainstay in the treatment will always lie in the domain of hydrotherapy and here cold packs followed in from one to two hours by friction will be most serviceable. Other measures are cold Preissnitz applications to the abdomen and cold sitz baths. Where the insomnia is accompanied by painful sensations in the back and extremities or where there is also chronic constipation or habitual congestion of the head vibration massage is often a valuable adjunct The same may be said of general faradization, which is usually better than galvanization. Many patients will do well at the seashore, but the severer cases are more rapidly improved in woody or moderately elevated places. A proper resort must be selected for each individual case. In all, a quiet life free from all excitement must be possible. The same may be said of the various watering-places which have been recommended. There remain two further therapeutic measures—hypnotism which is an excellent remedy, though there are many in whom the hypotic trance cannot be induced, and the use of drugs other than hypnotics which must aim to remove the cause of the nervous condition.

PATHOLOGY AND BACTERIOLOGY.

Relation of Renal Disease to the Circulatory System.—The primary effect of kidney disease is obstruction of the circulation in the capillaries and arterioles. Considerable discussion has appeared on whether the cause lay in the contraction of the capillaries or arterioles. W. H. BROADBENT (Practitioner, Nov., 1901) believes that the condition of the capillary contraction controls physiologically the amount of osmosis and following the law of capillary attraction and repulsion the amount of resistance depends largely upon the character of the contained fluid. The retinal hemorrhages present in such small vessels can be due only to increased pressure within them which must be the result of obstruction beyond them, or in the capillaries. A similar conclusion is suggested by a study of cerebral hemorrhages. Given this resistance to the normal flow there must be increased power to drive the blood onward and hence the hypertrophy of the heart. Greater force from behind causes high pressure in the intervening arteries and hence the high-tension pulse. In detecting this change the point to observe is the fulness of the artery between beats, the absence of the sudden subsidence as the wave passes. Constant high pressure later leads to muscular hypertrophy and finally degeneration of the arterial walls and heart, the various symptoms which arise depending upon whether one or the other part of the system gives out first. Broadbent believes that the convulsions are due to high intercranial pressure. Convulsions may occur in association with high arterial tension when there is no renal disease. There does not seem to be any relation between the amount of urea or nitrogenous waste matters in the blood and convulsions. Free venesection is, therefore, strongly indicated in a case of uremic convulsions. Again, he believes that Cheyne-Stokes breathing results from high arterial pressure as it has been an invariable antecedent of this phenomenon, in his experience, whether or not there has been albuminuria. Mercurial aperients, he finds, act best in relieving high arterial pressure. Five grains of calomel or pil. hydrargyri with colocynth and hyoscyamus, given three times a week, act very favorably.

Action of Ferments and Diastases on Tuberculous Poisons.—The action of the various body ferments and diastases upon tuberculous poisons and the bacillus tuberculosis is of interest as a further step in the solution of the tuberculosis question. G. CARRIERE (Archiv. de Méd. Experimentale, Nov., 1901) has taken up this subject experimentally. He finds that ptyalin, pepsin, trypsin and bile act upon cultures of the bacillus tuberculosis by extracting a poisonous substance from the body of this organism. Cultures submitted to the action of these substances possess a greater toxicity than those not so treated. When such cultures are inoculated into tuberculous guinea-pigs they do not prevent the evolution of the disease. They possess no immunizing properties. So far as the bodies of the organisms which are thus acted upon are concerned, he finds that the tulu oil extract of such is very toxic, but less so than that obtained from the bodies of these bacilli which have not been submitted to the action of these substances. Thus these ferments take away a certain portion of the toxins present in the bodies of these organisms. This tulu extract upon animal inoculation possesses neither curative nor immunizing properties.

Tuberculin Reaction as a Method for Ascertaining the Infectiousness of Cow's Milk.—Of late much doubt has been expressed with respect to the value of the tuberculin reaction as an exclusive method for determining the infectious properties, so far as tuberculosis is concerned, of cow's milk. Considerable experimental work has been done upon this subject by Rabinowitsch and Kempner. The most recent work, however, comes from OSTERTAG (Z'tschrift. f. Hygiene und Inf., Nov. 22, 1901). His observations were confined to sixteen cows. These were examined for the presence of the tuberculin reaction and clinical evidences of tuberculosis. The milk was examined microscopically for tubercle bacilli. In every case where the organisms were not thus found the milk was inoculated subcutaneously into guinea-pigs. In this manner it was possible to ascertain absolutely whether or not tubercle bacilli were present. The results show that the milk of cows which distinctly react to tuberculin, but exhibit no clinical evidences of tuberculosis never contains tubercle bacilli and hence cannot be a source of tuberculous infection. Calves and swine may be fed for weeks and months on such milk without developing any signs of tuberculosis. The presence of suppurative udder tuberculosis is the surest guide to the infectiousness of the milk. In all cases where such was present tubercle bacilli were found in the milk.

Contribution to the Biology of the Gonococcus.—It is a well-known fact that the gonococcus ceases to grow well on artificial media if the temperature is only several degrees higher than that of the human body. To ascertain if an increased body temperature will in a like way act detrimentally to the germ, G. NOBL (Wiener klin. Rundsch., Nov. 17 and 24, 1901) examined a number of cases in which gonorrhea complicated other febrile conditions. These were in three cases typhoid, in one pneumonia and in one pulmonary tuberculosis, and the author found that even with 41°

C. numerous gonococci were found in the urethral secretion which were capable of active division on proper culture media. The reason probably is that the latter can never replace the favorable conditions for microorganismal growth which exist in the urethra, despite the increased temperature.

Nature of Amyloid Degeneration.—The various theories concerning the origin of amyloid tissue are given in full by F. BROWICS (Klin-therap. Woch., Nov. 17 and 24, 1901). He himself believes that amyloidosis is due to an infiltration of the tissues with chemically altered erythrocytes or to a heaping up of these owing to slowing of the blood-stream in the capillaries and altered physical properties of the cells that result therefrom. Hyaline degeneration is explained on a similar basis and not regarded as an early stage of amyloid change.

Tumors of the Kidney.—Of the various tumors which occur in the kidney two important classes may be distinguished, according to D. VON HAUSEMANN (Zeitschrift f. klin. Med., Vol. 44, Nos. 1 and 2), namely, those directly renal in origin and those which take their start from displaced suprarenal tissue. Of the first class lipomata deserve only a passing notice since they are small cortical growths of no clinical importance. Papillomata are much more common and are as a rule also unimportant, though they have been known to assume large dimensions and even to invade the vena cava and cause malignant metastases. According to whether the papillæ are poorly or strongly developed, two classes may be distinguished. In the malignant varieties the papillæ are generally long and slender. Adenomatous tumors are very rarely met with in the kidney and many described are in reality hypernephromata, *i. e.*, suprarenal in character. The true adenomata are generally tubular in structure and do not attain a large size, while the hypernephromata are situated near the surface of the cortex, manifest their malignancy by rapidly encroaching upon the surrounding tissue and undergoing fatty degeneration, so that eventually large tumors with soft, yellowish interior and cysts filled with turbid fluid are formed. They may, however, run an extremely chronic course. Though generally sharply circumscribed, they may well destroy the remaining renal tissue by coinpression. Often a very careful histological examination will be necessary to reveal suprarenal structure. They share the property of other malignant renal growths in that they show a tendency to perforate into the renal vessels and inferior vena cava. The following eight points have been given as characteristic for them and distinguishing them from other renal tumors: (1) Their cortical position and macroscopic appearance; (2) their sharp encapsulation; (3) the property of the nucleoli to stain differently from the nuclei; (4) the structure of the cell-protoplasm, dependent chiefly upon fatty inclusions; (5) their similarity to malignant tissues starting from the suprarenals directly; (6) the presence of giant-cells; (7) their tendency to perforate the veins early, and (8) their property to produce glycogen. Endotheliomata also occur in the kidneys; they were formerly classed as hemangiomata and lymphangiomata. True carcinomata may be medullary, more rarely scirrhus or colloid in character, and may remain circumscribed or grow more diffusely when the kidney retains its normal shape, but enlarge considerably. Both forms may penetrate into the renal pelvis, when villous excrescences form which fill this and the ureter and metastases not infrequently form in the opposite organ. Sarcomata are more rare and generally of the spindle-cell type; they tend to infiltrate and the uninvaded renal tissue will often be found to functionate perfectly. Barring only the unimportant fibroid growths, they are the only tumors developing from the stroma. Lastly, mention must be made of teratoid growths which also may take on malignant characters and form metastases.

A New Hemoglobinometer.—The chief disadvantage which is common to all hemaglobinometers in general use is that the colors compared are never exactly of the same tint and hence the reading of the percentage is more or less a matter of guesswork. G. GAERTNER (Münch. med. Woch., Dec. 10, 1901) has constructed a new instrument which he calls hemophotograph which depends upon the principle that the greater the concentration of a solution of blood the more will the actinic rays of the spectrum be absorbed by it and hence the less intense will be the darkening of photographic paper placed underneath the solution and exposed to light. The advantages claimed are (1) comparison of identical tints; (2) great sensitiveness; (3) simplicity of the instrument; (4) permanency of the estimation, since the photographic paper can be added to the patient's history and referred to at a later date; (5) cheapness of the apparatus.

Predisposition of the Apex for Tuberculosis.—Faulty development of the first rib, which, when marked, goes hand in hand with a flattening of the upper half of the thorax and leads to the formation of a furrow near the apex, is considered by L. SCHMORL (Münch. med. Woch., Dec. 10, 1901) as the chief predisposing cause for this portion of the lung to become tuberculous. Owing to the constant pressure there will be disturbances in the circulation of the blood and lymph and poor development, or misplacement of the posterior branch of the apical bronchus will lead to improper ventilation of this part of the lung and hence retention of secretion.

Antiseptic Properties of Uric Acid.—As a result of his experiments, E. BENDIX (Zeitschrift f. klin. Med., Vol. 44, Nos. 1 and 2) comes to the conclusion that the supposed antiseptic properties of uric acid, which are considered to render impossible suppuration and tuberculosis in those afflicted with gout, do not exist, for, on adding either uric acid or the more soluble urate of sodium to cultures of various bacteria, their growth was in no way inhibited. The rarity of tuberculosis in the gouty may be due to the fact that the latter are, owing to their constitution, not liable to become consumptives, and the difficulty with which gouty joints become septic may be explained by the inability of the bacteria and their toxin to penetrate the hardened tissues.

Experimental Hemoglobinuria Caused by a Bacterial Toxin.—The injection into the blood stream of substances which have a solvent effect on the red blood-corpuscles gives rise to hemoglobinuria. A series of hemolysins have been previously described as produced by various organisms, *e. g.*, bacillus pyocyaneus, staphylococcus aureus and albus, bacillus diphtheriæ, streptococcus pyogenes, bacillus typhosus, etc. But the feeble hemolytic action of these pathogenic organisms is masked by more obvious symptoms. A more suitable organism for the study of experimental hemoglobinuria is the bacillus megatherium, which produces substances which are powerfully hemolytic without causing death or serious illness. The hemolytic action of this bacillus was first observed by C. TODD (The Lancet, Dec. 14, 1901), who obtained a culture of the bacillus from hay infusion, another from a sample of papain powder, and a third from Gral of Prague. The three races were grown in Erlenmeyer flasks at 37° C.

and the hemolytic power of the cultures tested daily on a 5-per-cent. suspension of guinea-pigs' washed corpuscles in 0.75-per-cent. saline. The formation of the hemolysin is in the main extra-bacillary; it begins between the second and third days, reaching the maximum on the sixth or seventh day. Oxygen is essential to the formation of the hemolysin, though some growth takes place anaerobically. A high degree of alkalinity favors the production of the lysin. The corpuscles of the guinea-pig and of man are highly sensitive to the lysin; those of the donkey and horse are practically unaffected. In the case of megatheriolysin various normal sera exercise a considerable anti-hemolytic action. The fact that a widely-distributed organism, which has hitherto been regarded as non-pathogenic, is capable of forming products bringing about in susceptible animals such profound blood-changes is of great interest. The results of Todd's experiments are suggestive in connection with the pathology of such diseases as blackwater fever, paroxysmal hemoglobinuria and pernicious anemia.

The Bacillus of Dysentery.—In the summer of 1899 Roger isolated a bacillus from dysenteric stools during an epidemic of that disease at Finisterre. MOREUL and RIEUX (Comptes Soc. Biol., Dec. 6, 1901) during the recent epidemic in Algiers isolated an organism in all cases examined, which they consider identical with that discovered by Roger. They also found it in the stools of several endemic cases examined. The bacillus is often associated with other organisms present in such stools. The rule is, however, that the more severe the case the greater is the number of these bacilli and the less the number of other organisms present. In several very severe cases pure cultures of this bacillus were obtained from the stools. They describe it as very similar in morphology to the bacillus coli communis. It stains easily with all the aniline dyes. It retains Gram's stain. The optimum temperature for its growth is 38° to 40° C., but it can be cultivated at 44° to 45° C. It is extremely motile, often nearly as much so as the typhoid bacillus. It grows well in bouillon, does not liquefy gelatin, forms a thin brown layer on potato, ferments sugars and does not produce indol. It is pathogenic for guinea-pigs and rabbits. It is agglutinated by the blood of animals immunized against it and occasionally by experimental typhoid serum, but only in a low dilution and the reaction is not typical.

Identification of the Colon Bacillus by Means of the Neutral Red Reaction.—It has been stated by several authorities that neutral red agar is a good medium for differentiating the bacillus coli communis from the typhoid bacillus in that the former changes the color to a canary yellow, while the latter produces no such effect. It has been claimed that the presence of colon bacilli in water may be easily demonstrated by merely inoculating such agar with a portion of the water and obtaining the reaction. R. C. ROSENBERGER (Pro. Phila. Path. Soc., Nov., 1901) has recently reviewed this subject experimentally. His work shows that neutral red agar while not affording a specific reaction in the case of the bacillus coli communis should be classified as a valuable differentiating medium. The typhoid bacillus while it does cause a fading of this medium never gives rise to the fluorescence noticed in some cultures of the colon bacillus. This test should not be depended upon as the only differentiating one in the examination of water as several very common bacteria found in such give rise to the same reaction.

Intracellular Constituents of the Typhoid Bacillus.—The essential functions of life are based upon intracellular phenomena and the great aim of biological inquiry at the present time is to obtain a more intimate knowledge of the vital processes of the cell. ALLAN MACFADYEN and SYDNEY ROWLAND (C'tlblt. f. Bäk., Dec. 5, 1901) have taken up this line of research from a fresh standpoint, viz., the study of the intracellular factors in health and disease by obtaining directly the cell substance from the living cell and eliminating so far as possible excreted substances and those formed by the cell in a given environment. For the extraction of the cellular substance of the typhoid bacillus they employed a technic which involved the trituration of the organisms in the presence of cold. In this manner the injurious effects of heat upon the substances present in the cell protoplasm are avoided. The cellular substance thus obtained was submitted to animal experimentation. The inoculation of such into guinea-pigs, rabbits and monkeys is regularly followed by the appearance of agglutinins in their blood. All the animals, but especially the guinea-pigs, showed a marked tolerance for this typhoid cell juice. In all cases the inoculations were followed by marked immunization and the animals were thus easily protected against lethal doses. The same result was obtained when the juice had been preserved for months by the use of thymol. It has also been ascertained that the typhoid bacillus produces hemolysin in various culture media. Thus, the bacilli grown in spleen juice to which serum has been added produce hemolysin in eight days. The endeavors to demonstrate the production of a soluble toxin by the typhoid bacillus have not been successful. If the symptoms of typhoid fever are due to an intoxication as well as to infection the detection of the toxin would mark a great advance in the treatment of the disease by inoculation. All that can be said at present is that if the bacillus produces a soluble toxin ordinary laboratory culture media are not suitable vehicles for its origin. Even when cultivated in fresh juices from various organs of the body, the production of a soluble toxin cannot be demonstrated.

An Electro-Thermal Paraffin Bath.—Since the very broad introduction of electricity into laboratories and establishments in general where scientific work is being done, to the greater or less exclusion of gas, it has become imperatively necessary that some form of electrical regulator be devised. One for which much accuracy is claimed is technically described by its inventor. R. H. STEEN (Brit. Med. Jour., Dec. 14, 1901). The heat is furnished by a pair of ordinary incandescent lamps in which the current is closed and broken by the movement of a cleverly-devised armature which, in its turn, is governed by the expansion and contraction of a column of mercury. This thermostat is very delicate; it holds a temperature so even that no variation is indicated by an ordinary thermometer. This regulator will be welcomed by not a few who have been told that an electrical apparatus which should be reliable was an impossibility.

Biologic Test for Semen.—A test of practical value for the detection of the nature of suspected seminal spots has been proposed by C. G. FARNUM (Jour. Amer. Med. Assoc., Dec. 28, 1901). The test is based on the fact that if bacterial filtrates, peptone, milk, egg-albumin, albuminous urine, blood-serum, etc., are injected at intervals for a period of time, they produce substances in the blood of the animal which form specific precipitates with the substances injected. After experiments made with animal semen, it was also found that the blood serum of rabbits treated with human semen gives a distinct reaction (precipitate) with both recent and old emulsions of human semen in salt

solution, also with human semen which had been dried and preserved thirty-four days on filter-paper and on cloth. But with emulsions of bull, of dog, and of goat testicles no reaction took place. With human blood serum, human semen gives no precipitates. At present it is probably safe to conclude that blood sera treated with different semens and testicular emulsions contain specific precipitins. That the substance which gives rise to the precipitin is contained in the semen itself seems probable from the absence of precipitate in human serum to which is added the serum of rabbit treated with human semen.

GENITO-URINARY AND SKIN.

Skin Eruptions in Renal Disease.—The correlation between skin and kidney lesions has been considered one of undoubted fact for hundreds of years and yet later authorities, according to J. J. PRINGLE (Practitioner, Nov., 1901), have found that it is the exception rather than the rule that the various skin eruptions have any relation to renal disease. The skin eruptions which are connected with nephritic conditions may be classified as those of the early stage, such as pruritus, urticaria and eczema; those in the final stage, such as the universal erythematous bullous or disquamative eruptions, and the purpuric and other hemorrhagic eruptions. Dieulafoy in 1882 made the important observation that pruritus is often an early, or, indeed, the first, symptom of Bright's. It may present all degrees of severity, from a mere localized itching, often about the legs, to an intense and unceasing torture. Urticaria as a symptom of Bright's is very rare, and even eczema is not thought to be more common in patients suffering from albuminuria than in others. Thursfield and Pye-Smith express similar views. Erythema papulatum uræmicum is the most characteristic skin affection the relation of which to renal disease is established, but it is rare. It consists of numerous large papules or nodules with a red areola arising upon an erythematous base, subsequently becoming deeper in color. It begins on the extensor surface of the arms and may spread over the entire body. General bullous eruptions are very rare. Hemorrhages into the skin as well as other tissues of the body are, of course, very common. Boils, carbuncles and ecthymatous lesions are also common, as in diabetes. The cause of these eruptions is unknown, but it is thought that they are similar to those caused in septicemia or ptomain-poisoning, toxins acting through the vasomotor and trophic nerve systems. It is certain that uric acid and urea are not the toxic agents, and it is thought that substances of the aromatic group which reduce Fehling's solution are the offending agents.

Cold in the Treatment of Skin Affections.—In a series of cases comprising lichen planus, eczema lichenoides and herpes tonsurans, E. SAALFELD (Therap. Monatshefte, 1901, S. 356) successfully utilized liquid air to freeze the diseased areas as a means of cure. The spot to which the extreme cold is applied promptly swells; then a white wheal with erythematous border is formed, and after a few hours an acantholytic bleb develops. Within three weeks normal white skin covers the treated area. After early trials with liquid air, Saalfeld adopted as a freezing agent a mixture of chlorethyl with chlormethyl, a much less expensive remedy than liquid air. With this mixture the parts are sprayed for a period varying from thirty to ninety seconds after the appearance of the icy incrustation.

Early Diagnosis of Tuberculosis of the Bladder.—Even the most skilful microscopist may be unable to find tubercle bacilli in the urine in the early stages of tuberculosis of the bladder. In this event the clinician may turn to animal inoculation as an aid to diagnosis, but, as this method can yield no results for several weeks, P. ASCH (Berl. klin. Woch., Nov. 18, 1901) recommends early cystoscopy. It is true that the influence of cystoscopy on the tuberculous process in advanced cases is detrimental to the patient; this, however, is not true, according to Asch, in the early stage of a tubereulous cystitis, when diagnosis without this aid may be impossible. The principal facts in a typical case described by its author are as follows: Frequent urination, often painful; urine constantly clear, free from albumin and sugar; microscopically, the centrifuged urine showed red blood-cells; cystoscopic examination revealed a long ulcer with swollen borders and white central deposit situated about the mouth of the left ureter.

Pleuritic Urticaria.—This phenomenon has been observed occasionally in pleurisy with effusion, and most frequently appears after thoracentesis, according to G. MINCIOTTI (Gazz. degli Osped., No. 135, Nov. 10, 1901). Its appearance at this time is explained by the fact that the upper strata of the exudate is withdrawn, while the deeper portion, containing micro-organisms and their products, remains. This latter, in course of absorption, is taken up by the lymphatics, producing an intoxication of the system, with a consequent toxic urticaria. The eruption seems to bear a certain relation to the rapidity with which the exudate is absorbed. Observers of the phenomenon believe that the earlier the appearance of the eruption and the greater its intensity, the more promptly does absorption take place. Treatment of the dermatosis is considered unnecessary.

Dermatitis Gangrenosa.—A case of this rather rare disease, beginning as a pustular rash, impetigo, is described by J. M. FINNEY (Dublin Jour. of the Med. Sciences, Dec., 1901). In three weeks the pustules had become deep and wide ulcers, and a destructive panophthalmitis had set in. There was a deep contrast between the raw-meat color of the floor of the ulcers, the purplish red shade of their edges, and the fair skin of the body. There was no evidence to associate the disease with vaccination or varicella. Tubercles were found in the thymus gland and lungs. The disease is most common in females, does not seem to be contagious, but is often fatal.

OBSTETRICS AND GYNECOLOGY.

Proper Method of Protecting the Perineum.—It is well known that when Nature is left to herself during the expulsion of a child the percentage of ruptured perinei is very large. The method of supporting the perineum which has been in vogue at the Sloane Hospital for many years is given by L. E. NORFLEET (Med. Rec., Dec. 21, 1901). The aim throughout is to allow the head to advance very slowly and gradually, permitting the perineum time to become relaxed and stretched. The patient's bowels should always be emptied. When the head comes down on the perineum the right hand should be placed flat against the perineum, the fingers on one side, the thumb on the other side of the vulva. The left hand holding the occiput from above, with the right hand from below, is entirely sufficient to control the advance of the head. As soon as the forehead can be felt behind the anus and held from slipping back into the vagina between pains, chloroform should be given until the advance of the child can be entirely governed by the accoucheur. Chloroform may be given earlier in the second stage if the pains are very severe. When the patient is under the influence of the chloroform, by pushing the forehead upward toward the pubes and if

necessary stimulating contractions of the uterus slightly with the left elbow, the head may be slowly "shelled" over the perineum and a tear very seldom results.

An Extraordinary Case of Artificial Respiration.—A well-developed male child was delivered with forceps under chloroform at full term by J. J. REDFERN and G. NEWBY (Brit. Med. Jour., Dec. 14, 1901). The case was not one which presented any unusual difficulty. The cord was twice around the neck and respiration after delivery was entirely absent. All the more usual methods of excitation were used without avail. Intubation failing in the absence of a sufficiently small tube, tracheotomy was performed and a catheter introduced into the trachea. After an hour's work a bicycle pump was connected with the tube; later a pair of small hand bellows was found to work better. At the end of two hours and a half the first inspiratory act was noted. During all this time the heart's action had been entirely under the control of the bellows operator and averaged from 50 to 100 beats. After six hours respiration gradually failed and at the thirteenth hour the child died. The points of unusual interest are (1) the fact that the heart continued to beat for two hours and a half without any voluntary respiratory effort; (2) increased use of the bellows produced marked quickening of the pulse-rate; (3) the child never gave any other sign of life than action of the heart and lungs and clonic spasms of the right hand. The cause of respiratory failure involves the following possibilities: (1) Possible pressure on the vagus or phrenic nerves by the double cast of the cord around the neck; (2) chloroform poisoning by absorption from the mother; (3) injury to the respiratory center through pressure by the forceps on the child's head.

Fetal Placental Circulation.—The relation between the circulation of the maternal and fetal blood within the placenta has long been an interesting subject and has lately been settled beyond reasonable doubt on the point that the blood of the mother does not enter the vessels of the child. B. S. SCHULTZ (Centrablbl. f. Gynäk., Dec. 7, 1901) presents an interesting and simple method of proving this fact. A fresh placenta is taken and floated upon a dish full of warm water with the maternal surface uppermost. The umbilical vein is dissected out of the cord and provided with a cannula. Through this warm milk is run until a high degree of pressure is obtained. It will then be found that the exposed surface of the placenta is entirely free of milk although the head of that fluid has been sufficient to squeeze out blood from the vessels of the maternal surface. It will be found that the placenta will erect itself, so to speak, take on the full form which it had in the uterus, even to becoming concave toward its fetal aspect. While making these changes in position and form blood will continue to flow from the vessels of the maternal surface, but milk does not escape. Furthermore, the separate cotyledons of the organ begin to appear discrete from each other and still the injecting fluid remains entirely within the fetal circulation. If at this point one of the cotyledons is cut with a knife an active stream of milk with oozing will appear. It is best to select the vein for this injection because of its comparatively wider distribution in the organ than the arteries themselves, and also because its lumen remains comparatively larger than the lumen of the arteries and therefore permits the milk to flow more freely. This is a simple and effective means of demonstrating that mother blood and child blood are separate throughout intra-uterine life. It therefore follows that when the child perishes through early separation of the placenta from the uterine wall, death does not occur through lack of blood, as has ordinarily and for many years been held. When such separation occurs, the child does not lose a single drop of blood. Similarly, when a child is born apparently dead from the same cause, it is not from hemorrhage, but rather from deficient aeration of the blood that its condition is at all serious.

Dysmenorrhea.—Any new method of treating this troublesome and common condition is usually tried with enthusiasm. A. THEILHABER (Centralbl. f. Gynäk., Dec. 7, 1901) brings out the following facts regarding the etiology and antomical foundation of the trouble A submucous myoma is a common cause and always produces exceedingly painful contractions of the uterus between and during menstruation. It is especially during menstruation that the womb is excited and that this foreign body provokes greatest trouble. Perimetritis is also a very usual factor in exciting dysmenorrhea. In perhaps more than three-quarters of the cases either one or the other of these two elements is present. The other patients suffer more or less from purely functional derangements. Under this heading must be numbered the various kinds and degrees of displacements of the uterus. The precise seat of the pain is probably in the cervix at the circular muscle bands about the internal os. A condition of tetanic contraction of these bands must be exceedingly painful as is shown also by similar conditions in spasm of the pylorus, and of the cardiac end of the stomach, of the intestines, and of the anus. The exciting factors of such spasms in the womb are nervous conditions like hysteria, neurasthenia, mental disturbances, various forms of sexual abuse and others. In the treatment of this condition, the aim should be to overcome the cause, when one can be definitely assigned. The new method which he proposes to follow out is a step in addition to that which he enunciated not long ago, which consisted in dilating and dividing these muscle bands with the hope that their reunion would be imperfect enough to stop the trouble. He now aims not only to dilate and divide, but also to remove this circular layer *in toto*. In order to avoid cutting away too much tissue, he has devised an ingenious knife which is not unlike a potato-parer. The blade is 1 dec., 5 cm. long, with a little slot in its center, one edge of which is lower than the other and sharpened. The blade is concave away from the edge of the knife. After the canal has been dilated or cut enough to permit the introduction of this blade, it is carried around, pressing the knife firmly against the mucous membrane. The cutting edge projects 6 mm. below the surface of the instrument, so that it is impossible to cut away more than this amount. The author states that the instrument works quickly, directly, thoroughly, safely and gives results that are very promising.

Pessaries in Prolapse.—Artificial means of holding up the uterus in prolapse of the uterus and of the vagina are valuable only when the patient cannot be, for any systemic reason, operated on. A large number of pessaries have been devised for all purpose, and this is one of the most fertile fields both for their invention and for their use. W. ROSENFELD (Centralbl. f. Gynäk., Dec. 7, 1901) presents one for which he claims great advantages. It consists in, first, a funnel-shaped cup, aimed in its size and form to fit over the cervix and be retained there by suction. Drainage is secured by five or six rather large holes. From the center of this cup passes a stem, in length varying according to the size of the vagina and other conditions. This is the second part of the instrument and is provided with a generous drainage hole. Its diameter is, relative to that of the cup, rather small. After the uterus has

been replaced manually the pessary is introduced in such a manner that the walls of the vagina fall about it and the cup is held against the cervix by the fornices. The stem is now left free to move about more or less in the vagina according to the bladder and rectum being full or empty and according to the position of the patient. Like all pessaries the instrument needs watching. The author claims that, in point of efficacy and convenience, when properly applied and thereafter cared for, it is superior to all others that he has used.

Pregnancy and Albuminuria.—Recently the belief that lesions of the kidney are entirely responsible for the presence of albuminuria during pregnancy, and especially the eclamptic seizures, has been much modified by valuable investigations. D. BERRY-HART (Practitioner, Dec., 1901) briefly reviews Schmorl's work to show that eclampsia is due to a strong irritant developed in connection with the placenta, causing degenerative changes in the liver, lungs, and heart, as well as the kidneys, and hence albuminuria is only one symptom of a systemic toxemia. This irritant he believes to be a fibrin ferment derived from placental giant cells. This advance in pathology has led to a modification of the treatment of eclampsia and an avoidance of violent and depressing remedies is particularly urged. We must remember that various organs are undergoing changes, that the nature of the irritant is still hypothetical, and that we still do not know by what organ it is eliminated, if eliminated at all. When albumin is found, a milk diet, rest in bed, attention to the bowels and an occasional hot bath are all that is usually necessary. If headache and eye-symptoms supervene induction of labor is indicated. If eclampsia has occurred, powerful purgatives, pilocarpine and venesection should be abandoned as being too depressant. Chloroform is very valuable and should be given at once to control the seizures. Begin with hypodermic injections of morphine, gr. ⅓ to ½ and gr. ¼, repeated in two or three hours if necessary. The morphine treatment was first started in Germany, but is now fairly well accepted in England. The effect of morphine is more lasting than that of chloroform and constant attention is not so essential. A large saline by bowel should next be given or an intravenous injection in very severe cases. Hot packs are beneficial, but oxygen inhalations seem to do little good. A minimum of judicious treatment seems most successful. Labor should be accelerated, but the rapid methods of Dührssen and Cæsarian section are seldom necessary.

EYE, EAR, NOSE, AND THROAT.

Ocular Symptoms in Bright's Disease.—These symptoms are divided by W. H. H. JESSOP (Practitioner, Dec., 1901) into three groups: (1) Those to be seen externally; (2) those seen by the ophthalmoscope, and (3) uremic amaurosis. The naked eye appearances are those of edema of the lids, especially the lower, which is usually temporary. The conjunctiva may show a bright, shining, watery appearance and subconjunctival hemorrhages are rather frequent. The retinitis of Bright's is usually bilateral. Its severity is no clue to the intensity of the kidney trouble nor the amount of albumin in the urine. Vision, as a rule, is not much affected, except when optic neuritis, extensive hemorrhages or changes around the yellow spot are present. In chronic nephritis, especially in granular kidney, the vision tends gradually and steadily to deteriorate, but total blindness seldom occurs. The appearances of the background vary considerably and no picture may be said to be pathognomonic. The picture may vary according as the white spots and plaques, retinal effusion, hemorrhages, vascular changes, and optic disc changes predominate. Diabetic retinitis is perhaps the lesion the most likely to be taken for Bright's. From statistics it would appear that very few cases live beyond two years after the retinitis has been diagnosed, and most cases with granular kidney die within a year. Uremic amaurosis is characterized by great loss of vision, sometimes amounting to complete blindness. As a rule, it comes on suddenly, clears up in one or two days and may or may not be accompanied by ophthalmoscopic changes.

Treatment of Empyema of the Antrum.—Excellent results in diagnosis and treatment of purulent conditions of the antrum of Highmore through the ostium or accessory openings are reported by N. H. PIERCE (Phil. Med. Jour., Dec. 21, 1901). These accessory openings are probably pathological, but still are quite constant and found in the middle meatus of the nose near the hiatus semilunaris. For washing out the sinus, a Schmidt's cannula is used, connected by a tube with a bulb syringe to a gallon percolator jar. The parts are anesthetized with cocaine or suprarenal extract, the point of the cannula introduced under illumination into the middle meatus, and the ostium or accessory openings felt for and entered. The irrigating fluids must be sterile and bland, such as Thiersch's solution, solutions of sodium bicarbonate, carbolic acid (2½ per cent.), boracic acid, or acetotartrate of aluminum. It is well to use this method before resorting to surgical puncture for diagnosis or treatment.

Mycosis of Pharynx and Base of the Tongue.—On account of the characteristic appearance of this condition, small pointed masses of milk-white color, projecting from the mucous membrane to the extent of an eighth of an inch, there ought not to be any serious difficulty in diagnosis and yet it is often treated for follicular tonsillitis or diphtheria. E. H. GRIFFIN (N. Y. Med. Jour., Dec. 14, 1901) shows how difficult the treatment of these cases sometimes becomes. The patient's throat was treated in succession by the application of chronic, carbolic, nitric and sulphuric acids, but these seemed to irritate the growth and produce an extension. Smoking seemed to retard the growth. Out of fifty cases treated the author has never seen it occur in a man and ascribes this to the prevalence of the smoking habit among men. By picking out each root with forceps and cauterizing with a bent probe with chromic acid a marked effect resulted, but not entirely satisfactory. The following prescription, at first used on account of anemia, really gave the best results:

℞ Tinct. chlor. ferri.....ʒ iij
Glycerini .....ʒ ij
Aquæ q.s. ad.....ʒ iij

Sig. One teaspoonful every three hours as a gargle, without water, and then swallow. The combination of this last method following the evulsion of the membrane and cauterization with chromic acid seemed very satisfactory.

MEDICINE.

Causes and Symptoms of Uremia.—Numerous theories have been advanced in regard to the cause of uremia, but none of them are entirely satisfactory. J. R. BRADFORD (Practitioner, Nov., 1901) reviews the experimental work that has been done and shows that the mere retention of normal constituents of the blood, even when both kidneys are removed, will not produce uremia. On the contrary, the animal or person dies in a condition of profound asthenia after several days of progressive weakness and diminution of temperature. The injection of urine into the blood causes

symptoms resembling uremia and, hence, the retention of toxic substances normally excreted in the urine has been given as a cause, but acute uremia frequently supervenes with little or no suppression and complete calculus suppression causes the symptoms of latent rather than acute uremia. We know that there is frequently an abnormally rapid wasting of the body in cases of nephritis, and it is suggested that owing to the renal disease the tissues undergo an anomalous metabolism with the formation of more or less toxic substances which are liberated in the blood-stream, and, owing to the impaired activity of the kidney, these substances may accumulate and give rise to uremia. Dyspnea is the most constant and one of the most important symptoms. In the acute uremia it may be of the hissing character described by Addison or of the Cheyne-Stokes variety. Convulsions may so closely resemble epileptiform seizures that the diagnosis is difficult, and no other symptoms of renal disease be present. The temperature in acute uremia is usually subnormal, but pyrexia and even hyperpyrexia may result from several seizures. In uremia the gums are usually spongy and bleed easily and the patient complains of an extremely offensive taste and smell in the mouth. Examination of the fundus oculi will almost always reveal papillitis or albuminuric retinitis, and acute uremia occurring during a chronic renal trouble will always show retinal changes. Acute uremia is more especially associated with chronic Bright's due to the form described as the contracted white kidney which often has an insidious onset with no dropsy and an abundance of urine containing considerable albumin.

Sepsis Due to the Colon Bacillus.—Two cases of sepsis in very young infants are reported by O. V. KOVALEVSKY and E. MORO (Klin-therap. Woch., Dec. 15, 1901) in which the colon bacillus was found as the cause. Both infants were brought to the clinic when only a few days old, suffering apparently from marasmus; in the first case the sepsis took its start from a severe cystitis with fibrinuria, followed by pyelonephritis and general invasion of the system, while in the second the primary focus could not be detected and jaundice with hemorrhages was a prominent sign. In both the colon bacillus was isolated from the blood after death and its identity established by serum reaction.

Roentgen Rays in Internal Medicine.—The value of the Roentgen rays as an aid in the diagnosis of affections other than surgical is ably discussed by H. HILDEBRAND (Münch. med. Woch., Dec. 3, 1901). In apical tuberculosis this method gives no better results than auscultation and percussion, since the proximity of the apex of the lungs to the clavicle and first rib gives but poor pictures and since the focus must be of considerable size to throw a perceptible shadow. The results are much more gratifying in gangrene of the lungs, since the exact locality can be determined and since, when multiple lesions are found, useless operation may be avoided. The same applies to echinococcus, tumors and foreign bodies in the lung, while the method offers no advantage in pneumonia or pleurisy, though in the latter a horizontal upper level would speak for hydro- or pyopneumothorax. In simple pneumothorax the differential diagnosis between this and bronchial stenosis and emphysema may be difficult; an X-ray picture will rapidly clear the diagnosis by showing the sharp border between the lung and the empty pleural sac. For diseases of the heart the Roentgen rays can be dispensed with. They are of considerable more value in the diagnosis of aneurism of the aorta, though an abnormal course of the aorta and mediastinal tumors in immediate proximity to the aorta may give similar pictures. It has been recommended to transilluminate the body in an oblique direction from below and to the left anteriorly to the right. By this method the esophagus gives no shadow, but stenoses and dilatations can be diagnosed by the introduction of sounds which throw shadows. Foreign bodies in the gullet are readily determined by the oblique method. Concerning the condition of the abdominal organs, the Roentgen rays have in the main been disappointing. Though the size of the stomach can be determined by filling this with bismuth or shot, the method is far too troublesome and disagreeable to be practical. The course and condition of the large intestines may be demonstrated by giving the patients bismuth for several days, but this, too, has little value. A fertile field for diagnosis, however, lies in the detection of calculi, especially the renal calculi, not uratic in composition. In the majority of instances a shadow will form, though a negative result does not speak conclusively for the absence of stones. Vesical and prostatic stones also readily show, but in the majority of cases the presence of gall-stones cannot be proven unless they contain a high percentage of carbonate of lime. Little value is to be expected from the Roentgen rays in diseases of the central nervous system, and their only slight value in such disorders as Pott's disease, chronic arthritis and osteomalacia must be mentioned for completeness. It is thus clear that while a great aid in diagnosis, too much has been expected of this method, in internal medicine at least.

Early Diagnosis of Tuberculosis.—It is of the greatest importance to detect tuberculosis in its incipiency and the various methods are reviewed by A. MOELLER (Münch. med. Woch., Dec. 10, 1901). The one most frequently practised is the examination of the sputum. If a wet pack be applied to the chest over night and the patient be rubbed thoroughly in the morning the findings will more often be positive. Another modification is to allow the sputum to stand for forty-eight hours at 37° C., when multiplication of the few bacilli present takes place and their detection is facilitated. If results are all negative there still remain the animal experiment and the tuberculous injection as diagnostic aids. The latter is free from danger if the old tuberculin is used and asepsis is practised. The proper dose to begin with is $^1/_{10}$ milligram and a rise of 0.5° C. is considered a reaction. If this does not take place, the dose must be gradually increased. The gastric irritation which may set in is readily controlled by diet and carminatives. The recently-advocated agglutination method has not stood the test of experience.

Diagnosis and Prognosis of Mixed Infections in Pulmonary Tuberculosis.—Much speculation has been indulged in with respect to the relations existing between the various micro-organisms present in the sputum in pulmonary tuberculosis and the bacteriological status of the lung infection. To this end CARL SPENGLER (Ctblt. f. Bak., Dec. 5, 1901) has examined microscopically the sputum of eleven cases of pulmonary tuberculosis and noted the various micro-organisms, in addition to the tubercle bacilli, found therein. The cases were then followed to autopsy and the exact bacteriological conditions of the lungs ascertained. He finds that the infective conditions in the lung are not only qualitatively, but also quantitatively expressed in the sputum. Thus by a microscopical examination of the same the presence and status of a mixed infection can be definitely determined. He divides such mixed infections into multiple, active and passive forms. The organisms found in addition to the tubercle bacillus are numerous but most frequent

are diplo-, tetra-, staphylo- and streptococci. Of especial importance are the streptococci and particularly the streptococcus longus. The appearance of this coccus in the sputum is always of unfavorable omen and is regularly accompanied by high fever and severe general symptoms. The prognostic value of the sputum examinations from this point of view is great.

Icterus and Weil's Disease.—The different forms of icterus, from the simple catarrhal to the toxic and infectious, have been subjects of much discussion. A. Michelazzi (Gazz. degli Osped., No. 144, Dec. 1, 1901) reports three cases, of paludal origin, characterized by the same symptoms in varying intensity. The three patients were fishermen, who, in the pursuit of their vocation, had been immersed to the waist for nearly an entire day in muddy, putrid water, subjected to the miasma arising therefrom. All three were taken ill a day or two after exposure. In explanation of the conclusions drawn from the three cases, the symptoms common to all, with differential points showing the variation in reaction to the infection, are given. Chill, fever, headache, muscular pains, meteorism, clay-colored stools, enlarged spleen, enlarged tender liver, and icterus. Case I., the mildest, no albumin in the urine, fever fell by crisis on the sixth day, rapid recovery after the tenth day. Case II., trace of albumin, spleen not enlarged, recovery after eleventh day. Case III., scanty urine, showing albumin and bile pigment in quantity, high fever, all symptoms more intense than in preceding cases, fall of fever by crisis on eleventh day; relapse upon the sixteenth day, with repetition of all symptoms in severity, equal to first illness. In the author's opinion, the clinical picture in the last case corresponds to the condition known as Weil's disease and the opinion of Patella is quoted, *i.e.*, that the latter condition is similar to, if not identical with, all forms of icterus characterized by a tendency to relapse. The conclusions drawn are that the same toxin, whatever its nature, may give rise to various forms of icterus, from the lightest to that presenting the symptomatology of Weil's disease, and that the latter should not be considered as a separate pathological entity, but rather as a severe form of recurrent icterus depending upon a greater receptivity of the organism subjected to the toxic influence.

A Typhoid Form of Generalized Staphylococcus Infection.—A number of these cases have been reported which resembled typhoid fever in a striking manner. The onset is accompanied by severe headache and nose-bleed, auscultation shows congestion at the bases of the lungs, the abdomen is distended, the spleen large, there is diarrhea, and Deslongchamps has even observed lenticular rose-spots. The onset is generally more rapid than in typhoid fever, chills more common, and albuminuria more intense and constant. E. Hirtz and G. Delamare (La Presse Médicale, Dec. 14, 1901) report such a case with necropsy. Coming on like typhoid fever, the signs of heart failure soon supervened. On the surface of the kidneys, the mucous membrane of the ileum near the cecum, and through the liver and spleen were scattered tiny white nodules surrounded by a hemorrhagic areola. Neither Peyer's patches nor the mesenteric lymph-nodes were affected. Microscopic examination showed the white nodules to be emboli of staphylococci, and these were found in the spinal cord and medulla oblongata, though not visible to the naked eye. There were no lesions of the myocardium except a single embolus, and the authors attribute the heart failure to the lesions of the bulb in which abscesses were beginning to form. The most common seat of infection in these cases is the skin (15 out of 25 cases), then in order the mucous membranes of the bronchi, digestive tract, uterus and urethra. The case reported lasted seventeen days.

Hysterical Perversion of Senses.—Various disturbances of sensation are met with in this most protean disease, but a very peculiar one has recently been reported by G. W. McCaskey (N. Y. Med. Jour., Dec. 14, 1901). Over the lower extremities there was analgesia and over the whole body the sensation to warmth was normal. The interesting part of the case was the remarkable disturbance of the sensibility to cold. Over the trunk and extremities cold was interpreted as heat and the colder the tube the hotter it seemed until ice water appeared to burn. Besides these changes in sensation there were several other stigmata of hysteria making the diagnosis certain.

Transmission of Yellow Fever.—Exceptions are taken by E. Souchon (Med. Rec., Dec. 28, 1901) in regard to a recent article by A. H. Doty, in which the latter concludes that "if ships from infected ports have been five days or more in transit and all on board are found to be well after a careful inspection and the use of the clinical thermometer, the vessel, its passengers and crew, shall be released without further detention or treatment." Dr. Souchon has been able to find thirteen cases in which the evidence seems to show that the disease developed at a later period than five days from infection or, at least, later than five days from the time the vessel left the infected port. As a single case brought into a southern port may prove most disastrous, Dr. Doty's rule is considered too lenient.

Amygdalotomy Rash.—The appearance of a rash following the removal of tonsils is seldom mentioned, but its possible presence should be known in order that a mistake in diagnosis be not made. E. A. Forsyth (N. Y. Med. Jour., Dec. 21, 1901) reports a case in which a small amount of cocaine was used and on the second day after operation a rash appeared on the face, neck and arms and the temperature rose slightly. Scarlet fever was diagnosed on account of the appearance of the rash, but it had entirely vanished in two days. It was thought that too little cocaine was used to account for the trouble. Browne and Wingrave are the only two writers that have ever mentioned such a rash, but they have seen a number of similar cases.

Initial Symptoms of Smallpox.—In a study of one hundred hospital cases of smallpox recently observed in Philadelphia the following facts were noted by W. M. Welch and J. F. Schamberg (Phil. Med. Jour., Dec. 21, 1901). Of the initial symptoms headache was most constant (86 per cent.), next chills or chilliness (78 per cent.), then backache (70 per cent.), vertigo (57 per cent.), nausea and vomiting (55 per cent). In point of time, chills were first observed in 35 cases, headache in 26, backache in 16, vomiting in 9, vertigo in 2. Severity varied, but in the severe cases, the initial symptom was always well marked. The death-rate was 22 per cent. It was also observed that in unmodified cases there was no marked remission of the fever until the second, third, or even fourth day of the eruption. In many cases, moreover, the early symptoms were interpreted as manifestations of typhoid.

Signs of Presenility.—Various symptoms of this rather frequent condition of the present generation are interestingly described by A. McL. Hamilton (Med. Rec., Dec. 28, 1901). Competition and ambition have led to a considerable increase in the mental and physical activity of the average man of to-day and undoubtedly the "strenuous life" has caused many an early "break-down." Mental impairment is one of the first defects noticed and manifests itself in various ways.

Slight emotion causes such persons to become flushed and irascible or to lose their patience. Hypochondriasis develops from that introspection which accompanies a limitation of brain power and easily-produced mental fag. He is indisposed to indulge in argument and arrives at results with the least effort possible. An early impairment of memory is especially annoying. Men between thirty and forty are liable to suffer from headaches of a peculiar kind, undoubtedly connected with changes in the size of cerebral vessels. The pain is suboccipital or frontal and usually bilateral. Many may first complain of what the writer believes to be an early symptom of cerebrospinal ischemia—cramps in the legs. This occurs most frequently at night and in the posterior leg muscles. Giddiness is also important and any unusual cardiac stimulation is liable to bring it on. A peculiar but fairly frequent kind of vertigo is described as the antero-posterior variety, as if "the blood was flowing from the front to the back of the brain." Consciousness is never lost and the state is not a persistent one, except in the matter of its frequent occurrence. Presenile insomnia is usually dependent upon an irritable brain. The avoidance of excesses of all kinds must be strongly urged in these cases, the regular use of considerable amounts of alcohol and tobacco leading to very harmful results by determining the blood supply to brain. Cerebral flushes are especially injurious. Each individual case must be managed according to the indications present, the regulations of one's habits being very important. A beneficial result is apt to follow the judicious use of the hot saline bath, a modification of the Nauheim treatment.

THERAPEUTICS.

Treatment of Paroxysmal Dyspnea in Aneurism of the Aortic Arch.—If purely spasmodic in character, due to reflex from irritation of the recurrent laryngeal nerve, this most distressing condition can be relieved, says F. BUSHNELL (Brit. Med. Jour., Dec. 7, 1901), by laryngotomy and anesthesia. Whether chloroform alone, without laryngotomy, would suffice must depend on the site of the irritation and on the state of the patient. It seems clear that, if the anesthetic did not at once relieve the laryngeal spasm, laryngotomy would have to be at once performed and artificial respiration, with the administration of an anesthetic, resorted to. In many cases the administration of chloroform and amyl nitrite give immediate though unhappily not lasting relief.

Treatment of Abortion.—This term is usually applied to the throwing off of the impregnated ovum at any time from conception till the complete formation of the placenta. H. HUGHES (N. Y. Med. Jour., Dec. 21, 1901) divides it into criminal and simple accidental, the latter of which may be either complete or incomplete. In a case of threatened abortion the patient should be put to bed and at rest, both physically and mentally. Morphine also should be used to quiet the uterus. If abortion becomes evident from the persistence of pain and hemorrhage, any attempt to prevent expulsion may prove harmful. The indications then are to stimulate the pains and control the hemorrhage, and the tampon is by far the most efficient agent for this. Almost any kind of gauze may do, or strips of old muslin, but they must be sterile. Fineness of texture is also important. The rectum should be emptied; a vaginal douche is not usually necessary. The external parts are scrubbed, a drain-pad is adjusted, and a sterile speculum inserted. One piece of gauze is introduced into the cervix which is then closely packed around with gauze and the whole vagina firmly filled with the sterile material. Considerable pressure is needed for if it is not firm the packing will be worse than useless. The succeeding pains are for the patient's benefit and the gauze is generally removed when the pains cease, but it may be left in for twenty-four hours. Retamponing may be necessary, but the fetus is usually found on the gauze or in the vagina on removal of the tampon. In incomplete abortion removal of the secundines is necessary and the patient is prepared as before. Tenacula are used to bring down the cervix, some dilatation may be necessary and a blunt curette is employed to clean the uterus, which is subsequently washed out with creolin, one-half per cent. The vagina is then lightly packed with gauze. To relieve the pain and restlessness the following may be used:

℞ Morphine sulph.....gr. 1/6
Chloral hydrate.....gr. x
Sod. brom.....gr. x
Water .....oz. ij

Criminal abortion must always be considered as septic. Curettage should be done, followed by douching and packing with iodoform gauze which is left in for six to eight hours. In these cases one's own reputation must be carefully guarded.

Rectal Serumtherapy.—Early in 1896 M. Chantemesse reported his experience, which was most favorable, with this mode of treatment in twenty cases. E. W. COLLINS (Brit. Med. Jour., Dec. 7, 1901) adds some cases of his own and confirms the French observations. In a very severe case of erysipelas of the face he gave antistreptococcus serum by rectum, 10 c.c. each twenty-four hours for three doses. In this case, and in all his diphtheria cases, the result was immediate. The advantages of this mode of administration are a rapidity of absorption almost equal to that of subcutaneous injection without subsequent unpleasant or untoward effects, such as pyrexia, joint pains or skin eruptions. The rectal dose should not exceed that of the subcutaneous injection.

Treatment of Diabetes Mellitus.—To facilitate the discussion of the treatment of diabetes, R. LEPINE (Wiener med. Blät., Nov. 28 and Dec. 5, 1901) divides the patients into (1) diabetics without and (2) those with diacetic acid in the urine. The former class admits of a subdivision into those (*a*) in which the glycosuria disappears after careful dieting, and (*b*) those in which it persists, and the latter into (*a*) those in which the diaceturia readily yields, and (*b*) those in which all treatment is unsuccessful in removing it. Where dieting only is necessary, the ingestion for three days of only proteids and fat will generally suffice to obtain a urine free from sugar, and it is only necessary to keep the patient for several weeks on this diet and then gradually to add carbohydrates. Much more serious are those cases in which the glycosuria persists. Here the absolute meat diet has been advocated, but this irritates the kidneys and increases the albuminuria, enhances the liabilities of diacetic-acid formation, and even leads to more marked glycosuria. It is therefore necessary to reduce albuminous food and to add fat, although this in large amounts may meet with resistance on the part of the patient and may also form a source for acetone. Concerning the second class of cases, various drugs may diminish the acid dyscrasia: of these bicarbonate of soda and gluconic acid are the most valuable and have been known to tide over attacks of coma. The increased consumption of carbohydrates may also lead to an improvement in, or disappearance of, the acid.

Fatty Heart.—The modern conception of the term fatty heart is summed up by C. HIRSCH (Münch. med. Woch., Nov. 19, 1901) as follows: (1) A fatty

heart as a disease *sui generis* does not exist and the term should be altered into cardiac disturbances of the obese. (2) If an obese person under forty years of age, with poorly-developed musculature, shows symptoms of cardiac weakness, the disproportion between the size of the body and the force of heart must be considered as first cause, but others such as coronary sclerosis, or severe functional trouble must be excluded. (3) In the obese of all ages with strong musculature it is more probable that coronary sclerosis, renal changes, arteriosclerosis of the splanchnic vessels or chronic myocarditis is present to account for the symptoms.

Treatment of Anthrax.—The injection of 5 c.c. of a 1-per-cent. solution of collargol directly into the veins has been tried by D. FISCHER (Münch. med. Woch., Nov. 19, 1901) with excellent results in a case of anthrax. After several hours restfulness and spontaneous sleep, with free perspiration, set in and the local symptoms soon abated. Disadvantages were not noticed and the chill by which the injections are sometimes followed can be obviated by carefully freeing the solution from undissolved or precipitated particles of silver.

Fersan in Anemia.—Some excellent results with fersan in the treatment of anemias are reported by A. BASS (Centralbl. f. d. gesamt. Therap., Dec., 1901). A very interesting case is mentioned in which a severe anemia followed gastric dilatation owing to pyloric stricture. Although only one-tenth of the amount of fersan administered passed the pylorus and was absorbed, after five weeks the patient had an almost normal amount of hemaglobin and could with safety be operated upon. The usual daily dose should be about fifteen grams.

Treatment of Cyclic Albuminuria.—After a full meal, after the taking of drugs, such as urea and acetate of potassium, which act as diuretics, after hot baths and with the patient for some time in a horizontal position, P. EDEL (Münch. med. Woch., Nov. 12 and 19, 1901) found in all cases in conjunction with pale and abundant urine a diminution or entire disappearance of albumin. Of greater importance is the fact that exercise, when taken vigorously and with interest, acts in the same way. It is therefore important in treating these cases to resort to dietetic measures and to systematic exercise for heart and respiration. The symptoms of malaise and general weakness of the heart, so often found late in the forenoon, have led the author to give more food during this time and to recommend proper exercise with excellent result. A cautious training of the heart within the same limitations as apply to purely cardiac patients also does good in patients with organic renal disease.

Treatment of Bright's Disease.—In the treatment of acute cases of nephritis W. H. WHITE (Practitioner, Dec., 1901) recommends rest in bed as the most important factor. There is nothing better for keeping the skin at a uniform temperature than a bed, and in acute cases the relationship between the skin and kidneys is especially delicate. The room should be kept constantly at 65° F. and the patient not allowed out of bed or at least out of the room. The diet should always be milk, because it is a simple diet and does not contain anything to irritate the kidneys; it is particularly suitable for fevers, and, lastly, because it is a fluid diet and in acute Bright's it is important to wash out the kidney tubules. For this same purpose large quantities of water have been recommended, but excessive use of water has been found to materially increase the nitrogen excretion. Alcohol is bad for acute cases and so are strong diuretics, but acetate or citrate of potash may be given. Hydragogue cathartics are to be prescribed and frequent sweats produced, subsequent chilling being especially avoided. The best hypnotic is chloralamide in twenty- to thirty-grain doses. During convalescence a very careful return to a more general diet should be made and life in a mild climate should be insisted upon for a time if possible. In cases of chronic tubal nephritis the most striking thing is the extent of effusion of fluid into the connective tissues. This may be partly relieved by rest in bed and purgation. In obstinate cases acupuncture is considered safe if done with surgical precautions. Numerous punctures are made with a triangular needle and a sterile dressing applied and frequently changed. These cases are often kept too rigorously to milk. A feeling of depression and a soft feeble pulse usually mean that a little meat, bread and butter would be helpful. In chronic interstitial nephritis the great essential is to relieve the kidneys as much as possible and therefore the skin must be kept warm and never chilled. Flannels are necessary and a warm climate in winter. Some mineral water containing sulphate of magnesium acts best perhaps to keep the bowels in order. Many false ideas in regard to the diet of these cases have been inherited, the chief object being to diminish the risk of uremia and the percentage of albumin in the urine. The author has paid especial attention to these points in a large number of cases in Guy's Hospital and concludes that "there is no doubt that patients feel better and stronger on a full diet or a nitrogenous diet, such as chicken or fish, than on milk or farinaceous diet, and the liability to uremia is not increased by the more general diet." If the patient is loosing flesh, fats and carbohydrates are desirable. If the pulse tension is low and there is cardiac weakness, meat and beef tea are indicated, for the extractives are strong cardiac stimulants. If the pulse tension is high and the heart hypertrophied extractives are dangerous and may induce cerebral hemorrhage. Thus also a weak heart may do well with a little alcohol, but usually this drug is contra-indicated. Albuminuria in itself is of but little harm to the patient. It has been estimated that even a fifth of the boys at a large public school pass albumin in their urine. In cases of nephritis treatment directed to the diminution of the albumin is unscientific. Furthermore, the author has been unable to discover that the administration of milk in any certain way led to the diminution of the albumin in the urine. The chief guide to the diet should be the state of the pulse.

Potato Diet in Diabetes.—Besides the amylaceous substance which potatoes contain, the water and salts are important. If a person eat potatoes weighing three times as much as the bread ordinarily consumed, says A. MOSSÉ (Bull. de l'Acad. de Méd., Dec. 10, 1901), he will have taken six times as much water and three times as much salt as when living on ordinary bread diet, while the quantity of albuminoid and starchy food will remain the same. The salts of potatoes are chiefly salts of potassium, consisting of potassium in combination with organic acids; these are transformed in the organism into potassium carbonate. Potato diet therefore may be regarded as a sort of alkaline cure, the potassium acting favorably upon the glycolytic function. In 19 out of 20 cases of diabetes reported by MOSSÉ, the substitution of potatoes for bread was followed by a rapid diminution of thirst and glycosuria, and in fact by a general amelioration of the symptom-complex of the disease. The quantity of potatoes administered daily was from 600 grams to three kilos.

The Sanatorium Treatment of Phthisis.—"In our treatment of disease we should realize more fully that the action of pure fresh air is directly curative." These

are the emphatic closing words of an admirable article by R. W. PHILIP (Brit. Med. Jour., Dec. 14, 1901) and embody the essence of the treatment given at the Edinburgh Sanatoria. That this method holds out by far the greatest hope to those infected with tuberculosis is reached by the following conclusions: (1) General condition of the patient. Naturally, it is to the gain in weight that one must look for the most striking evidence of improvement. In the sanatoria good solid tissue is built, both muscle and fat in normal proportion. A gain of sixty pounds within the short space of six months is not unusual. (2) Temperature. The effects of this physiologic, dietetic, open-air treatment is noteworthy. It is very rare to find any pyrexial disturbance among the patients of a properly managed sanatorium. This is not because the lungs have returned to a normal state. On the contrary, they frequently present all the classic signs of cavity formation. (3) Circulation. There are few more beautiful phenomena than the change effected by a physiological life. Within a week or two and sometimes after a few days the rapid soft pulse is replaced by a slowed and resistant beat. The degree to which this is established is to be regarded as of very immediate prognostic value. (4) Alimentary disturbances. Measures directed toward improving the appetite are commonly needless, for it usually returns quickly under the new mode of life. (5) Night-sweats. In no one symptom does the return to a physiological life show itself more markedly or happily. This classic symptom disappears so surely that a continuance of it is to be attributed to ignorance or culpability of those in charge. The conception of pulmonary tuberculosis in the past has been and still is by many too much that of a localized lung disease, while the constitutional condition has been insufficiently considered. So far as treatment goes, the reverse must be the case. The systemic disturbance is immense. To combat this successfully means a vast systemic reformation. A return to the physiological life must be the aim of treatment, whether conducted in a sanatorium or at home. The open or sanatorium treatment has come to stay because it cures and it cures because it is physiological.

THERAPEUTIC HINTS.

Sodium Citrate in Diabetes.—This drug in dosage of 5-10 grams (3j¼-3ijss) has been found by P. DALCHÉ and M. CARTERET (Bull. générale de Thérapeutique, Nov. 8, 1901) to be a valuable adjuvant to more powerful remedies in causing a diminished excretion of sugar. It does not upset the stomach, as its decomposition sets free citric acid which is well borne. It may cause diarrhea. In the urine, besides loosening the sugar, it causes decrease in the urea, and increase in the phosphates and chlorides.

Hermophenol.—Hermophenol, the mercury phenol disulfonate of sodium, is a white powder of saline taste, and soluble in five parts of water. It does not precipitate albumin and is not decomposed by soda, hydrochloric acid or ammonium sulphide. It can be heated to 120° C. (248° F.) without change. The mercury salts, as a rule, precipitate albumin, irritate mucous membranes, retard rather than favor, cicatrization, and are painful in hypodermic injection. The gallate, succinate, sulfovinate, etc., organic salts designed to lack these objectionable properties, are no better than the sublimate. Other organic compounds, such as the salicylate, benzoate, peptonate, etc., do not precipitate like the ordinary mercury salts, yet are mostly inferior to the sublimate in solubility, antiseptic properties and content of mercury. A one-per-cent. solution of hermophenol will quickly destroy micro-organisms and only slowly affects the skin. A solution 1 to 500 can be kept in prolonged contact with the skin or mucous membranes without harm and can be injected hypodermically without abscess formation. Bérard is using wipes, tampons, compresses, etc., made of gauze or cotton soaked in a one-per-cent. solution and then sterilized. He has had no inflammatory reaction from application to a peritoneal surface. He employs a 1-to-30 solution for the eyes of all new-born and in ophthalmia neonatorum. He also uses for his hands a soap containing one per cent. of hermophenol, as this salt retains its activity in the presence of soap. Reynès treats his syphilitics by injections every 2 or 3 days of 4 cc. (3i) of a half-per-cent. solution. The effects are those of the best mercurial, without abscess or other unpleasant sequelæ.—A. MARTINET in La Presse Médicale, Dec. 11, 1901.

Emulsion of Salol.—In certain cases it is advantageous to use salol internally in the form of an emulsion. The following preparation, taken alone or in milk, is recommended in the treatment of gonorrhea and cystitis; each teaspoonful containing 50 centigrams of salol:

℞ Salol 4.0
Gum arabic..... 4.0
Gum tragacanth..... 0.20
Tr. tolu..... 10.0
Simple syrup..... 30.0
Distilled water q.s.

—Jour. d. Méd. d. Paris, Dec. 8, 1901.

Bronchitis with Bronchoplegia.—In treating bronchitis the two general indications are to lessen the cough and diminish the bronchial secretion. But a third indication, sometimes of great importance, is to combat bronchoplegia, the paralysis of the smooth muscles of the bronchi. This may be due to the toxins of certain infectious diseases, diphtheria, influenza, etc., or may be produced by mechanical causes in the course of chronic bronchitis. There is gradual progressive dyspnea with ineffectual cough, accumulation of secretions and congestion. In such a condition an opiate or other sedative might do great harm, drugs that will stimulate the nervous system and reawaken the bronchial contractility being required. A cardio-tonic and hemostatic pill of value is:

℞ Ext. hyoscyami.....0.3 (gr. v.)
Quin. sulph.....1.5 (gr. xxiv.)
Ergotin .....3.0 (gr. xlv.)
M. Ft. pil. No. xxx. Six or eight pills a day.

Rénaut's treatment of bronchitis is to give balsamics (terpin, syrup of tolu or Canada balsam, Venice turpentine, etc.) for the first four days; then for three days to give ergotin in suppository with opium or hyoscyamus, and at the same time pills of

℞ Ext. hyoscyami.....0.3 (gr. v.)
Terpin .....3.0 (gr. xlv.)
Ergotin .....1.5 (gr. xxiv.)
M. Div. in pil. No. xxx. Two or three a day.

In the bronchoplegia of grip, strychnine is the most useful remedy:

℞ Strych. sulph.....0.03 (gr. ss.)
Ergotin .....1.5 (gr. xxiv.)
Quinin. sulph.....3.0 (gr. xlv.)
M. Div. in pil. No. xxx. Take every two hours with a hot infusion sweetened with syrup of tolu and containing a teaspoonful of old brandy.—A. MARTINET in La Presse Médicale, Dec. 14, 1901.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

ASSOCIATION MEDICAL DEFENCE.

The adoption of the report of the committee of the New York County Medical Association appointed to draft a scheme for organized medical defence in suits for alleged malpractice makes the first step in an important practical movement that will undoubtedly redound greatly to the benefit of the medical profession. Only last week the *Journal of the American Medical Association,* after reviewing legal decisions in several States that show the permissibility of the formal insurance of practitioners of medicine and surgery by special insurance companies, asked the question, "Would it be practicable and advisable for the State societies of the American Medical Association to take up this work and such profits as may accrue be kept in the profession and not be allowed to outside companies."

The New York County Association makes the first practical response to this question and the details of the scheme of defence organization as presented seem to promise that the difficulties in the matter have been thought out and provided for.

This is a step in the right direction. Undoubtedly the knowledge of union among physicians for defensive purposes will deter many blackmailers from attempting to annoy practitioners into settlement in preference to expensive and time-taking litigation. Lawyers, too, will feel much less like encouraging clients to bring suit unless there is really some good reason. Moreover, such suits will lose much of their personal character. Prosecution will not be attempted for motives of spite and the general public will come to recognize the fact that legal entanglements are not due to deficient knowledge or blameworthy neglect, but to the inevitable uncertainty of human ailments.

The movement thus initiated promises to do more for effective solidarity among the members of the medical profession than almost any other feature of association work. It remains now that the details of the plan of medical defence shall be carefully elaborated and that the difficulties inevitably to be encountered in hitherto untried methods shall not be permitted to discourage those directly interested nor seriously hamper the assured eventual success of organized medical defence.

ELEMENTS WHICH ENTER INTO THE QUESTION OF PROGNOSIS.

It is a matter of the greatest importance to be able to give a clear and candid opinion as to the probable outcome of disease and injury. We become so accustomed to the appearances and the phenomena of disease that we sometimes forget (at least some of us do) the intensity of feeling of those who are looking to us for comfort and relief.

How much significance attaches to severe illness, not only in connection with the one who is sick, but with the larger or smaller circle of those who may be associated with or dependent upon the sick one, no one can realize, and, coupled with this, is the distressing thought that we are always hedged in by the limitations of human knowledge and attainments. The doctor's opinion, whether he be the attending physician or the consultant, may be compared to an anchor or a rock to which the patient and his friends cling with desperation. It is at times pathetic to see the faith with which the physician's utterances are received. In the case of individuals of prominence how closely are the bulletins scanned and the opinions and prophecies of this or that attendant analyzed as if he were able to weigh the disease in all its variations!

In those cases in which the situation is sufficiently serious to cause anxiety there are at least

four propositions with which the physician is confronted and to which he is expected to give an answer. If he is unable to answer them himself, he asks for counsel, both for a division of the responsibility and to obtain light from another point of view. Of course, it does not follow that the consultant is any better informed or more competent than the attendant physician, but he has the advantage of considering the case with a freshness of vision which the latter may not have.

The first question which is asked when it is apparent that an individual is seriously sick is, Will he get well? Whether the case be a medical or a surgical one, this question may be an extremely difficult one to answer and in the case of certain severe diseases, especially the malignant ones in which operation may be out of the question or of very doubtful value, it is somewhat of an executioner's task to say, "No, the patient will not get well." What can be more distressing than to banish hope from the human heart? Many doctors have been called brusque and cruel because they have stated cold facts as they saw them. It is not necessary in prognosis to be rough or harsh, and if no ray of hope is apparent to the physician he ought at least to express his adverse opinion in the gentlest possible terms, and assist both patient and friends to meet the inevitable by all the art and tact which he can summon to his assistance.

The next question which must be answered is, How long will the sickness last? In the case of a probably or certainly fatal issue a truthful and correct answer is often very difficult. In the acute diseases a physician of experience may be able to forecast the result with considerable accuracy. In the chronic and malignant diseases it is often impossible to give expression to an opinion in set terms of months, weeks or days. It is certainly expected that an approximate answer will be given and one should at least be able to say within what limits the issue will be probable. If the result is likely to be favorable the requirements are not usually so exacting as in the case of a probably fatal result; but the wise physician should err in placing it at a remote rather than a near limit.

Another question which is of great importance concerns the occurrence of complications. Discredit often comes to the physician because he has not foreseen them, or has not considered it prudent to make such a fact known. It often happens, especially in surgical practice, that an uninterrupted and immediate recovery does not result, and disappointment or vexation may even lead the patient and his friends to question the skill and judgment of the attending physician. It is very desirable to forewarn them if such an issue may be expected. We all know that the best results of certain operations may not appear for six months or a year, and equally that the utmost skill and care may not forestall the necessity for a second operation. Patients should clearly understand this in the forecast which is made of the course and results of the treatment.

The fourth question which is usually asked, and especially in surgical work, concerns the possible return of the disease. It is certainly gratifying when one can give assurance that certain conditions when once removed will not return. However cheerful statistics may be made to appear, the average practitioner knows that the chances are against radical cure for malignant disease. It is also true that the results are sometimes better than our fears may lead us to expect. It is to the younger practitioner that the consideration of the various questions involved in prognosis is of especial importance. He will often make his reputation, good or bad, not alone by what he does but by what he says; and it will be of no little service to him if the opinion prevails that his judgment is acute and reliable, and that he can be depended upon to give a fair statement of the course which a given disease is liable to take.

NEEDLESS LAPAROTOMY.

SOME time ago the *British Medical Journal,* apropos of the frank confession of some diagnostic mistakes by surgeons, suggested that a meeting a year of medical and surgical societies at which only mistakes should be discussed would be an extremely valuable institution. It further suggested that, if deemed advisable, reporters should be excluded from this annual confessional meeting. To deprive the medical public of the benefit to be derived from such confessions would be too bad. *Erranda discimus,* we learn by erring, is as true now as when penned by the old Roman nearly 2,000 years ago. Happy the man who can learn from other peoples' mistakes. He is rare, of course, for personal experience is after all the only real teacher and only the exceptionally wise man ever learns from the mistaken experiences of others. The ideal in medical advance is, however, to profit by the errors of others and so we are glad to be able to present some account of certain entirely justifiable surgical mistakes that under the stimulus of the candidness of Dr. Munro of Boston were the subject of confession at the last meeting of the Har-

vard Society of New York (see Medical News for January 4th, p. 43).

Now that surgery and medicine overlap so extensively in the management of abdominal conditions, surgical findings in cases where diagnosis was at fault are especially suggestive to the medical man. There are many intra-abdominal affections whose differentiation one from another is most difficult. Appendicitis, right oophoritis, and certain biliary affections are liable to almost inextricable confusion in complicated or somewhat unusual cases. There are, however, other pathological conditions supposedly quite distinct in symptoms that may well prove sources of error.

The hope for advance in diagnosis depends mainly on frank confession of errors and the collation of cases that will show the reasons for such errors.

While peritonitis would seem to be, as it actually is in ordinary practice, an easily recognizable condition many an abdomen has been opened in the confident expectation of finding it present, yet the operator has been disappointed. Prof. Koenig of Berlin, an extremely conservative surgeon, exhibited a patient a short time ago before the Berlin Society of Physicians and Surgeons of the Charité Hospital on whom three laparotomies for peritonitis had been done in every instance to disclose an absolutely normal peritoneal cavity. The patient was a man and had some method by which his abdomen become tympanitic and his countenance took on the anxious expression characteristic of peritoneal inflammation, while he complained of all the subjective symptoms of the affection. Successive operators had found the old abdominal scar, but considered this an accessory indication for laparotomy since a second abdominal operation is proportionately more frequently necessary than a first one.

Where stigmata of hysteria exist, or where, as in one of Dr Munro's cases, the morphine habit is present, the possibility of simulation of what are ordinarily urgent surgical symptoms must be borne in mind. It is of extreme importance in our day of justifiable surgical readiness to do abdominal work, to be reminded that acute nephritis may so readily simulate appendicitis or surgical conditions in the biliary tract. For this kidney affection laparotomy can do no good and the effect of the operation will probably work serious injury. The exclusion of nephritis, then, in doubtful cases is absolutely demanded.

Two recent suggestions in kidney surgery, Dr. Reginald Harrison's splitting of the capsule for the acute congestion he picturesquely describes as glaucoma of the kidney, and Dr. Edebohl's establishment of a new circulation through adhesions in chronic nephritis must be borne in mind. At times inevitable laparotomies for symptoms whose basis is the kidney may thus prove not to have been needlessly done.

While there are needless laparotomies frequently performed there is no doubt that true conservatism will in the future lead to the performance of more rather than fewer abdominal operations. Many patients still die every year because of failure to attempt surgical relief in suitable cases. The frank report of errors will lead to a better state of mind and a surer diagnosis. Exploratory laparotomies may remain, in Dr. Manges expressive phrase, the "most dangerous of operations," because of the uncertainty involved, but the domain of uncertainty with regard to the indications for surgical interference will be constantly narrowed by the collation of actual experiences. No one is infallible, least of all in the applications of the eminently fallible principles of applied medicine, but we may rise on stepping-stones of past errors to higher things—from discouraging doubt to the comparative certainty that must remain as yet only the moral certitude of human concerns.

ECHOES AND NEWS.

NEW YORK.

New York Academy of Medicine.—The following candidates to resident fellowship of the Academy have been recommended: Drs. J. C. Ayer, Rudolf Denig, C. R. L. Putnam and P. F. Sondern.

German Medical Society.—At the last regular meeting of this Society, held January 6th, Dr. A. Schrapringer showed a case of Sach's family amaurotic idiocy and Dr. T. Bierhof exhibited a new ureter and irrigation cystoscope. Dr. L. A. Ewald read a paper on "Parametritis Posterior" and Dr. F. Maass a paper on "Operations on Nasal Tumors."

Preventive Medicine.—An opportunity to contribute to the literature of this important department of medical science, with the added incentive of a substantial reward if the work submitted is of noteworthy excellence, is given in an offer, made by the Maltine Manufacturing Company, of Brooklyn, of two prizes, one of $1,000 and one of $500, for the best essays on Preventive Medicine by a practising physician. The company has taken the precaution to exclude the commercial element by making it a condition of the competition that none of their products shall be mentioned, or even indirectly alluded to, and by securing as judges three physicians of unquestioned ethical standing, Drs. Daniel Lewis, of New York, Charles A. L. Reed, of Cincinnati, ex-president of the American Medical Association, and John Edwin Rhodes, of Chicago.

Police Surgeon Examination.—The examination for the position of police surgeon held before the Municipal Civil Service Commission on December 20th has been canceled, and a new examination has been ordered. A reading of the papers of the applicants, of whom there were ninety-seven, revealed some irregularities, with the result that each man who took part in the examination has received notice that a new examination is to be held on January 21, 1902, at 10 a. m.

Would Exclude Consumptives.—Residents of the towns of Liberty, Monticello and Rockland in Sullivan County have combined for the purpose of instituting a vigorous crusade against making these towns resorts for consumptives. Several months ago the Liberty health authorities passed an ordinance prohibiting expectoration in the streets, with a heavy fine attached, since which time tuberculosis patients have carried tin cups for the purpose. Now the town of Rockland Board of Health has passed the following resolution and the town of Liberty one similar to it: "*Resolved,* That no person shall maintain a public or private boarding-house or sanitarium within the limits of the town of Rockland for consumptives, neither shall he receive into his house any stranger or guest, other than his immediate relations or those depending upon him for support, who are suffering from consumption, under a penalty of $50." The village health authorities of Monticello have entered into the movement to the extent of requesting local real estate agents to discriminate against leasing properties to consumptives or their friends.

The New York Academy of Medicine.—A stated meeting will be held Thursday evening, January 16th, at which the following paper will be read: "The Food Factor as a Cause of Health and Disease during Childhood," by Joseph E. Winters, M.D. This will be discussed by Drs. Leroy Milton Yale, Wm. P. Northrup, John Dorning, Floyd M. Crandall, David Bovaird, Jr., Rowland G. Freeman, Allen M. Thomas, Thomas S. Southworth, and J. Milton Mabbott.

Surgical Section, New York Academy of Medicine.—The following is the program for the meeting to be held Monday, January 13th: Operation for Intra-Peritoneal Rupture of Bladder, by Dr. James Pedersen; Oöphorectomy for Inoperable Cancer of the Breast, by Dr. Franz Torek; Removal of Malar Bone for Epithelioma of Cheek, by Dr. C. H. Peck; Operation for Intra-Abdominal Omental Torsion, by Dr. H. Lilienthal; Removal of whole Omentum for Intra-Abdominal Torsion, by Dr. J. Wiener, Jr. Papers: "The Cure of Hydrocele by the Injection of Minute Amounts of Carbolic Acid," by Dr. W. B. Coley; "Clinical Memoranda in the Study of a Case of Anuria," by Dr. A. V. Moschcowitz; New Instrument to Increase the Safety of General Anesthesia, by Dr. Frederic Griffith.

Brooklyn Pathological Society.—At the last regular meeting, held January 9th, Dr. Glentworth R. Butler read a paper on "Pathology of Pleurisy and of Pneumonia." The discussion of its various phases was taken part in by Drs. E. H. Bartley, W. B. Brinsmade, E. H. Wilson, J. M. Van Cott, and J. R. Taylor.

PHILADELPHIA.

College of Physicians.—Officers elected at the January meeting of the College of Physicians are as follows: President, Horatio C. Wood; Vice-President, Arthur V. Meigs; Censors, Richard A. Cleemann, Arthur V. Meigs, S. Weir Mitchell, Horace Y. Evans; Secretary, Thomas R. Neilson; Treasurer, Richard H. Harte; Honorary Librarian, Frederick P. Henry; Councillors, John Chalmers DaCosta and J. P. Crozer Griffith.

Alpha Kappa Kappa Convention.—Physicians and medical students from various parts of the United States assembled in this city January 2d and 3d for the seventh annual convention of the Alpha Kappa Kappa Fraternity. The delegates were guests of the University of Pennsylvania and Jefferson Medical College chapters. The old officers were re-elected as follows: President, George Cook; Vice-President, John I. French; Secretary, John H. Collins; Treasurer, Edward R. Pfarre. At the annual banquet Dr. E. P. Davis acted as toastmaster, speeches being made by Drs. Cook, Wilson and Brace.

Health Report.—Influenza has again become prevalent, four deaths occurring from that disease during the week ending January 4th. For the same period there were 90 new cases of smallpox and 16 deaths. Five new cases of smallpox have occurred at the Philadelphia Hospital, making ten in all. The most active efforts are being made to avert an epidemic in the institution.

Obituary.—The remains of Dr. William Koonz, who died of injuries in the Philippines, were interred January 3d. Dr. Koonz was twenty-six years of age, going to the Philippines soon after his graduation. He died of blood-poisoning which developed from a slight wound on the chin received from a glancing bullet while attending a wounded soldier.

Dr. George W. Caldwell died from apoplexy January 1st.

Philadelphia Academy of Surgery.—At the monthly meeting, held January 6th, there were exhibited two cases of congenital misplacement of the scapula. Dr. W. Barton Hopkins reported a case of suture of tion. The case was that of a sailor who had a comthe acromioclavicular articulation for the cure of luxaplete luxation of four months' standing. The bones were cleaned to allow of perfect opposition and sutured by seven strands of silkwormgut used as one cord. They were introduced by making V-shaped borings in each bone with the points meeting at the line of juncture of the bones, thus forming an X of the entire suture. The result was in every way satisfactory, leading to the conclusion that at times it may be desirable to operate in cases of luxation of the clavicle.

The Annual Address in Surgery was delivered by Dr. Joseph M. Spellissy, his subject being "Abscesses in the Right Iliac Fossa of Other than Appendiceal or Gynecologic Origin." Dr. Spellissy enumerated the various structures in the right iliac fossa which may themselves be the seat of abscess-formation or the final lodging-place of pus having its origin elsewhere. Many cases were reported in which abscesses were due to disease of the vertebræ, sacro-iliac joint, ilium, femur, the muscles, nerves, foreign bodies, typhoid ulceration, etc. In view of the large variety of abscesses met with the question may be asked, "Is the diagnosis of appendicitis difficult?" Articles in the various leading textbooks of surgery were quoted to show the very meager space given to differential diagnosis. Dr. Spellissy stated that, because, as one prominent writer states, "the diagnosis of appendicitis is ordinarily easy," it gives the reason why mistakes are made in the cases referred to as simulating that condition. He concludes that the diagnosis of cases with symptoms referable to the right iliac fossa must be made in each instance with regard to the numerous structures of that region other than the appendix.

Dr. Thomas G. Morton read a statement regarding his first appendectomy following a definite diagnosis. This was performed by him on April 23, 1887, the diag-

nosis having been made before the operation, and was the first case of the kind on record. An appendix had been removed earlier in the year, but the diagnosis of appendicitis had not been first made. Dr. Morton reported the acknowledgment of his claim to priority by other writers who had recently been claiming that honor for themselves.

CHICAGO.

The Physical Effects of the Electrical Charge of Ions and the Electrical Character of Life Phenomena.—Dr. Jaques Loeb, Professor of Physiology in the University of Chicago, and Professor A. P. Matthews, Assistant Professor of Physiology in the same University, contributed a joint paper before the recent meeting of the American Physiological Society on this subject, of which the following is a brief abstract: The unfertilized egg dies soon. A fertilized egg will last for a much longer time. Professor Loeb finds that if the egg of the sea-urchin is treated with certain salts, it has the same effect as fertilization. From his experiments he is of the opinion that death is an active process. If it is not checked, it will lead to disintegration. He has poisoned eggs with potassium cyanide and then counteracted the effects of the poison. The results of the experiments with potassium cyanide have been far more impressive than he has ever dreamed. 'The poison acts as a preservative by hardening the outer coating. The eggs are taken as soon as they leave the ovary. Two processes are immediately set up. One is that toward death and the other is toward life. Unless some means are employed, the unfertilized eggs will soon die, the process toward death proving the stronger. The potassium cyanide in the experiments that have been made was used in small quantity. It cannot yet be said that in combinations of cells it would have the same effects, and a continuation of the potassium cyanide treatment does not yield the best results. The egg will take a certain quantity of the salt. It will in this manner be given a much longer life. Its life cannot be indefinitely lengthened by the use of the potassium cyanide, because other effects come in to hinder the action of the salt.

The energies of foodstuffs are supposed to generate from heat to mechanical force, yet the lower forms of life and organisms do not have a temperature above their surrounding atmosphere. It is admitted that electrical currents are the main, if not the universal, forms of stimulation, and he has come to the belief that at least a part of the energies of foodstuffs are turned into electrical forces. If one introduces electrically charged molecules in a body, there are interferences in tissue formations similar to those caused from a current of electricity being used. It has been demonstrated that the muscles of a jelly-fish contract when placed in electroids, but not when surrounded by a non-conductor.

Living matter is a liquid solution containing colored particles. Assuming that said particles have a charge of electricity, and that the liquid has an opposite charge, this would account for the fact that they are equally distributed throughout. By sending a current of electricity through the solution, it can readily be demonstrated whether negative or positive electricity prevails in the atoms. In an electro-positive solution, negatively charged ions may be inserted and the same results obtained. So electrically charged ions alter life. By experiment it has actually been shown that positively charged ions bring about or create life.

The joint contribution of Professors Loeb and Matthews may be summarized thus:

1. Motor nerves contain or consist of a colloidal solution, of which the colloidal particles carry positive electrical charges.

2. Nerve (protoplasm) is stimulated by the passage of the colloidal particles from a condition of a solution to that of gelation.

3. This change is brought about by the action of ions, namely, electrically charged atoms or groups of atoms, which bear negative charges. The stimulating action of any chemical compound depends on these negative charges. Those ions having one charge are less efficient than those with two or three.

4. The colloidal particles of the nerve are held in solution by positively charged ions, sodium, potassium, calcium, etc., and the effectiveness of these ions in preventing stimulation varies directly with the number of positive charges they bear.

5. By these facts chemical stimulation is shown to be identical with electrical. Whenever in any part of a nerve negative charges are in excess, the nerve is stimulated, namely, the colloids pass from a solution to a jelly. The stimulus always arises at the cathode.

6. The irritability of a nerve is diminished whenever the solution of the colloids is rendered more permanent. It increases as the nerve approaches the gelation state. All positively charged ions thus diminish the irritability; negative ions increase it. This explains electrotonus, namely, the irritability of the nerve is reduced near the anode, and increased at the cathode.

7. Heat diminishes the irritability of the nerve by rendering the solution more stable. Cold increases it by rendering it less stable. At high temperatures gelation (coagulation) takes place and the nerve is stimulated.

8. The nerve is stimulated mechanically because the colloidal particles are forced together. As they coalesce, their surface becomes less, less positive charges can reside on it, and part of the negative charges previously induced in the surrounding water are temporarily set free in their neighborhood.

9. The negative charges thus set free precipitate the next layer of colloids, which, in their turn, set free negative charges. This precipitates the next layer, and in this way the nerve impulse is carried. Technically, these negative charges are called the negative variation, and this stimulates each successive element of the nerve.

10. Anesthetics all dissolve fat. They reduce the irritability of the nerve or protoplasm, because the colloids in the nerve (protoplasm) are largely fat compounds and more soluble in a mixture of ether and water than in water alone. All anesthetics render the colloidal solution more permanent and prevent gelation.

11. Besides the number of electrical charges on the ions, there is some other factor which determines the action of the salts. Thus potassium is more effective in reducing irritability than sodium; fluorine is far more effective as a stimulant than chlorine, although all carry but a single charge. It is believed that this difference in efficiency in these monovalent anions or kations is dependent upon the rate of rotation of the electron, or the positive or negative point charge, about the atoms with which it is associated. The electron rotates about the fluorine atom about twice as fast as about the chlorine atom.

12. The stimulating action of any anion or the poisonous action of any kation is, hence, a function, first, of the number of charges revolving about the atom; second, of the rate of rotations of these charges; and, third, of the circumference of their orbits.

13. Chemical stimulation is thus by the electro-magnetic theory of life shown to be identical with stimulation by light waves. The stimulating action of any anion increases as the spectrum of that anion approaches the ultra-violet.

14. The long light waves and heat waves resemble in their action that of positively charged ions.

Antivivisectionists Criticized.—At a meeting of the American Society of Naturalists, held at the University of Chicago, Professor William T. Sedgwick, of Boston, not only condemned antivivisectionists, but he decried the influence of workers for physiological temperance in his paper who seek by legislation to turn text-books on physiology into temperance tracts for students. Among other things, he said: "The antivivisectionists have brought into subjection British animal physiology and principal experimental work in biological science. It is to our interest to see that American naturalists are not so hampered. No one in his senses desires vivisection in public schools, except possibly in normal schools, devoted to the education of teachers. Dissection of clams, sea-urchins and snails, and even fishes and frogs, is not out of place, and may be even desirable in high schools and normal schools. Efforts to restrict vivisection have been unsuccessful through the efforts of scientists aided by the President of Harvard, the President of the Massachusetts Institute of Technology, and the Bishop of Massachusetts. It was even proposed in this propaganda to take names of experimenters and in other ways interfere with the freedom of research. While we have cause to rejoice that we have resisted the onslaught of antivivisectionists, we confess with sorrow that we have been less fortunate with philanthropists in an important element of education. Scientific temperance instruction, which seeks to give young people a proper idea of the evils of alcohol has in some instances caused one-fourth of the space in text-books on physiology to be given over to a treatise on the harm of alcoholic beverages. Sometimes the authors of this branch of the work have been capable, and often they have been unfit for their task. The influence of this propaganda has been injurious to the proper teaching of physiology. Laws calling for portions of text-books to be given over to explanations of the harm of alcohol on the system are operating in nearly every State in the Union. It is odious that the exact amount of teaching should be prescribed by law. Text-books for students should not be controlled by a self-constituted and unofficial oligarchy, the leaders of a propaganda which is neither educational nor scientific. Naturalists should also guard against Christian Scientists who refuse to consider the benefits of medicine. Care should be taken that half-baked ideas should not be given force.

Crime in 1901 and Its Future.—Professor Cesare Lombroso has the following to say in one of our local newspapers regarding crime: "Organic crimes, the most atrocious and the most atavistic ones, have materially decreased, not only in number but in criminous intensity as well. One who has studied the most important criminal trials of recent years, like those of Daiming in Australia, Holmes in America, and Tiburzi in Italy, must have observed that the most atrocious and bloody crimes bear some intimate relation to fraud and robbery, and it is no longer pure ferocity nor thirst for blood which represents the motive of such crimes, but rather the greed of gold and that uncontrollable desire for pleasure that has given a special color to criminality and has converted the atavistic and simply brutal criminality into another kind, which might be called intellectual and less repugnant. One who has studied the criminality of London, and, better still, that of Australia, may observe in figures the evident thinning out of the bloody and revolting crimes. It is clearly shown that the crimes against the person numbering 84,000 in 1858 and 92,000 in 1872, fall to 78,000 in 1898. Thus the bloody crime diminishes to the extent of 8 per cent. Robbery and pocket-picking, 30 per cent.; counterfeiting, 34 per cent. But against this we have an increase of 27 per cent. in offences against property from 1878 to 1892, and an increase of 18 per cent. in offences against property based upon vengeance. But crimes against morality have increased from 530 in 1858 to 1,140 in 1898. In Australia, which represents a greater moral evolution than any other section of the world, indicating what the world will be fifty years hence, we see the crimes of blood descend from 182 in 1889 to 162 in 1898. Assassination is diminishing by one-half; stabbing has doubled and homicide has increased almost one-third. Theft in general has decreased from 574 to 394, while fraud and forgery almost one-half, or from 234 to 111; incendiarism from 23 to 16. Under any and all conditions a certain group of crimes of blood and theft still remain, because the degeneration which is favored by civilization, although it finds an outlet in suicides and insanity, will always give a quota, however scarce, of crimes, and a diminution of occasional causes, especially economic causes, will not eliminate all the counter-causes, which are not organic. As a matter of fact, and there is a lesson in these figures, out of 28,323 guilty Australians, 361 were arrested for the third time, 380 for the fourth time, 180 for the fifth time, and 174 for the sixth time, and 204 for between the seventh and the thirtieth time; and by considering the drunkards in a special class, we have 105 habitual criminals from five to ten times, and 18 from eleven to twenty-five times. Even in England the habitual criminal has increased from 55 for over 10,000,000 in 1863, to 60.2 in 1898, and in this calculation I do not include the suicides nor epileptic insane, who are, according to some authorities, a variety of criminality, and which is appallingly on the increase in the most civilized and enlightened countries. In conclusion, crime cannot disappear in the world, no matter what cure we apply to it, but all crimes, with the exception of those against women, will decrease in brutality and in number. We can now look forward to an epoch when the civilized world will consider crime as a strange expectation, as a monstrosity, which all the world will look upon with compassion, mixed with revolt and disgust.

Changes in Cook County Hospital.—The most important improvement made at the County Hospital during last year was the installation of a new heating-plant in accordance with the recommendations of the special commission that investigated the institution early in the year. Warden Healy reports that at present there are 797 patients in the hospital. During the year 20,218 other cases were treated, as follows: Surgical, 13,812; medical, 4,408; contagious, 693; obstetrical, 326; dressing, 979. The surgical cases were divided as follows: Operable, 4,095; general surgical, 8,724; eye, ear and nose, 256, and gynecological, 737. During the year 269 infants were born in the hospital. Supplies for the institution cost $178,201, and salaries, $117,210. The daily average of patients in the hospital during the year was 818, and the total cost for daily maintenance per capita was 98 cents. During the year many reforms have been put into effect by Warden Healy. Internes have been stopped from performing operations in the absence of a member of the attending staff; alcoholic patients have been debarred from the hospital; the doors have been locked against claim agents and solicitors; and a new system of registration has been adopted.

Public Health of Chicago.—The annual report for 1901 of the Chicago Health Department has just been issued. It is shown in the Department's report that Chicago's mortality for the first year of the twentieth century was more than 20 per cent. less than that of St. Louis; 25 per cent. less than that of Philadelphia;

nearly 28 per cent. less than that of Greater New York, exclusive of New York City proper; thirty per cent. less than that of Boston, and nearly 35 per cent. less than that of New York City. The most gratifying feature of Chicago's low death-rate is found in the steady reduction of infant and child mortality. This is directly attributable to the excellent work of the sanitarians connected with the Department. The deaths among those under five years of age in this city fell from 12,801 in 1891, to 8,282 in 1900. In proportion to population, this is a decrease from 110 to 49 per ten thousand, and in proportion to mortality it is a decrease from 46 to 33 per one thousand of the total deaths of all ages. This reduction still continues, and the report concludes that the completed records for 1901 will show fewer than 7,500 deaths under five years of age, or 42 in ten thousand of population, and fewer than 31 in every one thousand of the total deaths. The Department finds the causes for this diminishing mortality, not only among the young, but at all ages under sixty years, to be sanitation and preventive medicine. As to child-life, the causes for diminished mortality are given as the antitoxin treatment of diphtheria, a steadily improving quality of milk supply, medical inspection of the public schools, mid-summer work in the tenement districts, the growth of knowledge on the part of mothers as to care and nursing of the young, the labors of associations, clubs and settlements. In general terms, the diminished mortality is also largely due to permanent sanitary improvements. It will be still further reduced when the intercepting sewers are built and the full benefits of the drainage channel are realized. The report finds encouragement in the fact that even with a practically bankrupt treasury the city is pushing forward these permanent hygienic improvements. Special stress is laid upon the prospective value of the new smoke ordinance, which is designed to purify the city's air supply as the other and most costly enterprises are designed to purify the water supply. There are many other details in this voluminous report well worthy the attention of any man interested in the city's hygienic welfare and vital statistics.

Needs of Cook County Hospital.—Dr. Denslow Lewis, President of the attending staff of the Cook County Hospital, in a recent report to the County Board of Commissioners, made the following recommendations: (1) The construction of a separate building for skin and venereal cases. He suggests that a three-story building be erected, the first floor of which might be utilized by the County agent for the storage and distribution of supplies. (2) Some provision should be made by the proper authorities for the care of inebriates. This includes the victims of epilepsy, apoplexy, mild cases of insanity, heart or kidney disease, the sandbag or other form of assault or accident, who may be found unconscious on the public streets, and who are usually considered to be under the influence of alcohol. A separate building should be provided for the care of alcoholics, under the direction of the attending staff. (3) A children's pavilion apart from the hospital building is desirable. It is often advisable to permit the little patients to get out of doors, and for that reason their ward should be on the ground floor. (4) Provision for the X-ray work will have to be made. Probably $1,500 will be needed. The laboratory is now nearly completed and the funds from the sale of clinic tickets, together with the amounts received from voluntary reduction of salary on the part of the president and certain commissioners, will probably be sufficient for its maintenance. A photographic outfit will be needed later in the year. (5) A card index system for the proper compilation and preservation of the history sheets and other records is a necessity if periodical bulletins are to be issued showing the scientific work done at the hospital. The appropriation of $1,000 made for this purpose last year was not used because the laboratory was not completed, and it was impossible to furnish full reports of cases without instancing the pathological findings.

Vaccination Creed.—Health-Commissioner Reynolds has decided to issue a vaccination "creed," which is to be posted in boarding and lodging-houses. This method for combating the increase of smallpox was adopted by the Health officials recently. The creed calls the attention of inmates of lodging-houses to the value of vaccination. It says: (1) True vaccination, repeated until it no longer "takes," always prevents smallpox. Nothing else does. (2) True vaccination, that is, vaccination properly done on a clean arm with pure lymph and kept perfectly clean and unbroken afterward, never did and never will make a serious sore. (3) Such a vaccination leaves a characteristic scar, unlike that from any other cause, which is recognizable during life and is the only conclusive evidence of a successful vaccination. (4) No outward results ever follow such vaccination; on the other hand, thousands of lives are annually sacrificed through its neglect, a neglect begotten of want of knowledge.

Woman's Medical College to Close.—It is said that the Northwestern University Woman's Medical College will soon be abandoned, for the reason that Mr. Raymond and other trustees declare that the college runs behind about $25,000 a year. This college has not been well patronized of late owing to other schools adopting the plan of coeducation, and among these may be mentioned, Rush Medical College and the College of Physicians and Surgeons. Mr. Raymond is reported to have said: "It is impossible to make a doctor of a woman. Women cannot grasp the chemical and pharmaceutical laboratory work, the intricacies of surgery, or the minute work of dissecting. At our woman's medical department we do not get as high a class of scholarship as is set by the other colleges in the Northwestern University. Dr. R. B. Sheppard has been instructed to open negotiations for the sale of the buildings and grounds of the Woman's College of Medicine. The college was founded in 1870 by Dr. William H. Byford, and in 1891 it was purchased by the Northwestern and incorporated as a department of that University.

Northwestern Medical College Sold.—It is reported that the Northwestern Medical College has been sold to the Valparaiso, Ind., Normal School and the Chicago Eclectic Medical College. The purchase price is given as $40,000, each of the purchasers paying one-half. President Brown, of the Normal School, has guaranteed to furnish the new institution with at least 100 pupils a year, and the Eclectic College expects to be able to furnish as many more.

To Study Scarlet Fever.—There was incorporated at Springfield, Ill., January 4th, the Memorial Institute for Infectious Diseases, founded by Mr. and Mrs. Harold McCormick in memory of their son, John Rockefeller McCormick, who died just a year ago of scarlet fever. The institution has been endowed generously by Mr. and Mrs. McCormick, but for the present it will have no building of its own. At the beginning its researches will be devoted to scarlet fever solely and the work will be carried on in some other medical institution.

CANADA.

Montreal General Hospital.—The following statement for the month of December has been issued by

the officials of the Montreal General Hospital: The admissions into the various wards were 175; discharged, 159; deaths, 13; average daily sick in residence, 159; ambulance calls, 64. There has been a great falling off in outdoor work and in minor operations.

Appointments.—Dr. Doughty has been appointed assistant librarian of the Legislative Library of Quebec. Dr. William J. Abbott, B.A., Brockville, Ont., who is at present in England taking a post-graduate course, has been appointed to a professorship at Cornell University. Dr. Abbott, who is a graduate of Toronto University, will return during the present month to commence his duties.

Toronto Vital Statistics.—The vital statistics for Toronto for the year 1901 are as follows: Births, 4,445; marriages, 2,148; deaths, 3,438. The following are the numbers reported each year since 1893: Births, 4,064, 4,201, 4,131, 4,246, 4,046, 4,122, 4,007, 4,530, 4,445; marriages, 1,507, 1,456, 1,408, 1,601, 1,501, 1,696, 1,842, 1,789, 2,148; deaths, 3,426, 2,778, 2,986, 2,974, 3,125, 2,871, 3,294, 3,604, 3,438.

Smallpox Situation in St. John, N. B.—Under date January 4th, a despatch to the public press states that the people of St. John hope to see the end of the smallpox outbreak in that city at a very near date. Since the beginning of the outbreak three months ago, there have been 98 cases with 22 deaths. At the present time there are less than 30 people in quarantine, and of this number one-half of them have recovered.

Smallpox Situation in Montreal.—There are at the present time but 45 patients in the Civic Hospital, Montreal, with smallpox. At one time there were 71, so the outbreak is declining and the health officials believe they have the disease well under control. There are yet 19 houses quarantined.

Insane in Toronto Jail.—The Grand Jury of the County of York, Province of Ontario, has made a presentment in which they found that there are at the present time no less than 60 lunatics lying in the Toronto jail awaiting transference to some asylum, but as every one of these institutions in the Province is overcrowded, the present conditions will have to prevail until the new asylum at Coburg is opened for the reception of patients. In the House of Providence, the Jury found 20 consumptives being cared for, this being the only institution of a charitable character which would receive consumptives before the recent popular demand opened up the hospitals again to these unfortunates.

Toronto Over-run with Fakirs.—Toronto, usually, like any American city, has its proportion of charlatans, but at the present time there appears to be an epidemic of quackery abroad. Christian Scientists, osteopathists, palmists, spiritualists, and a new cult known as the "Radiators" are daily figuring in the annals of the Police Court, and the whole city seems to be literally infested with these people. The "Radiators" who have devised the "Radiant Health Circle" were making money until they ran foul of the Morality Inspector, who has had them convicted of obtaining money under false pretences and they are at present awaiting sentence. Some palmists are said to be making as high as $25 per day.

National Sanitarium Association's Report.—The medical superintendent of the Muskoka Cottage Sanitarium, Dr. J. H. Elliott, has handed out his report for the last official hospital year which ends September 30th. At the end of the previous hospital year 61 patients remained in residence and there were admitted during the year 127 patients. Of the 99 males treated during the year, 15 have been discharged apparently cured and 29 with the disease arrested. Of the 29, 14 gave promise of cure, but they could not remain longer. Of these 99 on admission, 24 were incipient cases; 43 advanced and 32 far advanced. The average gain in weight was 13 ounces.

Toronto Clinical Society.—At the regular meeting of this Society, held on the evening of the 3d inst, with the President, Dr. J. F. W. Ross, in the chair, Dr. George A. Peters reported three cases of more than passing interest. A specimen of a phosphatic calculus weighing six ounces was exhibited which Dr. Peters had removed by the suprapubic operation. Dr. Peters also described and illustrated his method of cutting calculi. The calculus is smeared over with a light coating of paraffin and then placed between the heels of a horseshoe lying flat on a board, 6 x 16 inches, at one end of it. The shoe and stone are then set in plaster of Paris, when sawing can be done from the end of the board toward which the heels point. Dr. Peters also reported two cases, one esophagostomy and the other dilatation of the esophagus. The first was rendered necessary in a young man who while drinking a cup of tea swallowed a small upper central dental plate with one tooth. This stuck in the esophagus near the cricoid and an operation for its removal was performed successfully. This was the second case of its kind recorded in the annals of any Toronto hospital. Dr. Peters' case of dilatation occurred in a farmer of thirty-five years. The dilatation occurred just above the diaphragm and was caused by compression of the two crura upon the walls of the esophagus. There was no malignancy. This patient died nine hours after a second operation. Dr. D. Campbell Meyers reported a case of peripheral neuritis which simulated tabes dorsalis, and recovery was noted under good doses of arsenic.

GENERAL.

Cancer Among Sailors.—The mortality from cancer among sailors is very high—44.5 per 100,000, while that of miners is only 12.2.

Health of the Philippine Islands.—The sanitary condition of Manila is not satisfactory, and probably will not become so until it is supplied with a satisfactory sewer system and a large number of the buildings remodeled. The city of Manila is located on a flat tract of land and, beside the river which flows through it there are several artificial waterways which connect with the river and into which a number of private water-closets empty. The foundations of most of the buildings consist of sandstone which becomes water-soaked from six to eight feet above the ground. A number of systems for disposing of the night soil, among which may be mentioned cesspools, stone vaults, and sewer systems connected with the river or bay, are unsatisfactory and the Board has recommended the introduction of the pail system until a proper sewer system can be instituted. Bubonic plague was first discovered in Manila in 1899 and up to the present time 778 cases have occurred, resulting in 618 deaths or 79.4 per cent. Great attention is at present directed toward the destruction of rats, which are believed to be the principal cause of the spread of the disease. But five deaths have resulted from smallpox in Manila during the last fiscal year, and the city is believed to be free from that disease. Pulmonary tuberculosis is found to be very common, 160 deaths having occurred during the past two months. This is regarded as a serious problem. Scarlet fever and diphtheria are rare, but measles is occasionally reported.

Rhinderpest and Locust Plague in the Philippines.—Rhinderpest has been prevalent among the cattle and caribou for a number of years and a large number of these animals have been destroyed. The Board of Health has taken the matter up and has sent experts into the provinces for the purpose of teaching intelligent natives the method of inoculating animals, which has resulted rather satisfactorily, and it is believed that in time the disease will be entirely eradicated from the Archipelago. The locust pest has likewise infested the Archipelago for a number of years, in certain instances destroying the crops and resulting in great suffering among the inhabitants.

A New Epidemic Disease Affecting Horses.—Since the invasion of the wet season in the Philippines, a large number of horses have been reported to be suffering from a febrile disease resulting in a great morality. This disease has been found generally present throughout the Island of Luzon, and in several localities all the native horses have died from it. A large number of Government horses also have been affected with this disease, but the mortality among them has not been so great as among native horses. As a rule, the disease appears suddenly and is not noted until too late to treat the animals. It is characterized by the following symptoms: Rise of temperature from 103° to 107° F., apparently without chill, increased abdominal breathing and full pulse. The temperature is rapidly followed by swellings of the pads under the belly, in the sheath, testicles and legs, and accompanied by heart failure and death in a number of cases. At times the disease is attended by emaciation, and may be accompanied by a convalescence of several months. On post-mortem examination, the organs and tissues, as a rule are anemic, in some cases abscesses are noted in the stomach and abdominal cavities; the pericardial sac and pleural cavities are always full of a serous fluid, but with no appearance of inflammatory changes. It does not seem probable that the disease is of a contagious nature, for in stables where there are a number of horses several may be affected while others remain immune. Microscopical examination shows an animal parasite, which shows active and definite movement and pseudopodia along the sides. The disease has proven an interesting one and is being investigated by the Board of Health, under the direction of the Superintendent of Government laboratories. A large number of specimens of blood taken from animals affected with the disease are at present being examined.

Antitoxin Institute.—An institute for the study and treatment of tuberculosis and other infectious diseases has been opened in Genoa by Prof. Maragliano. An antituberculous serum devised by him and prepared at the institute is offered to the medical profession. Prof. Maragliano holds that the remedies in common use, creosote, guaiacol, etc., have no antituberculous action, but that the benefits derived therefrom are due to their power over the secondary infections. Antitoxin is considered to act in the same way as do superalimentation, pure air, etc.; that is, by producing in the organism such changes as to give the blood-serum antitoxic power against the bacillus and its poisonous products.

Syphilis in Morocco.—This disease is widespread in Morocco; in the cities the natives follow the mercurial treatment prescribed by European physicians; but in the country, the treatment is entirely empirical. The patient is secluded in utter darkness for forty days; he is not allowed to eat beef, salt meat, nor olives, and only unleavened bread is allowed him. There is a sulphur spring near Fez which is much frequented by syphilities.

Hospital for Insane Burned.—One of the new buildings of the Eastern State Hospital for the Insane, at Williamsburg, Va., was burned January 4th. Inadequate fire-fighting facilities, together with the intense cold, made it difficult to cope with the flames. It is believed that several of the inmates perished, and a search of the ruins is being made.

For the Treatment of Consumption.—The King of England's application to anonymous persons for a gift of a million dollars to be devoted to the scientific treatment of consumption is generally applauded, and it is hoped that the next beneficent donor will remember the needs of cancer subjects.

The London Smallpox Scare Continues.—This past week 225 new cases were admitted to the hospitals, against 170, 134, and 161 in the previous three weeks. Yet London, despite the fact that it is the chosen home for the world's outcasts, keeps a lower death-rate than Birmingham, Liverpool, or Manchester, the rate for greater London being 19 last week. Moreover, while 665 smallpox cases were under treatment, the cases of scarlet fever were 3,137, and of diphtheria 1,381.

Pellagralogic Congress.—The second Pellagralogic Congress will be held at Bologna in May. The following are among the subjects to be discussed: (1) Relation Between Pellagra and the Price of Wheat and Corn; (2) Limitation of the Culture of Indian Corn; (3) Clinical Diagnosis of Pellagra; (4) Hygienic Supervision of the Turkish Grain, and Moderation of Its Consumption; (5) Legislation and Pellagra.

Alcohol and Prostitution.—A. Lutaud, discussing the repression of prostitution in France, makes the statement that alcoholism is one of the most profitable sources of income in the house of ill-fame. He quotes the resolutions passed by the French Antialcoholic Union at Lille, November 16, 1901, as follows: "Whereas the sale of alcoholic drinks constitutes a considerable source of revenue to the house of prostitution. (2) Whereas prostitution is in many instances but the unavowed pretext for the sale of intoxicants. (3) Whereas the unhappy women in such establishments are condemned to alcoholism without hope of release. (4) Whereas many among them, by reason of this condition, have the moral sense so blunted that they have no longer strength to escape from their lamentable condition. (5) Whereas suppression of the sale of spirits would have the effect, in many instances, of spontaneous closure of such resorts; be it resolved, that the Administration of Police and municipalities should make every effort to abolish the sale of alcohol in resorts for prostitution.

Eleventh Congress of Russian Physicians.—The Executive Committee announce that the eleventh congress of Russian Physicians and Naturalists will be opened January 2, 1902, at St. Petersburg.

Fourteenth International Congress of Medicine.—It is announced that the eleventh section of this congress, to be held April 23 to 30, 1902, will be subdivided into a department of otology and a department of rhinolaryngology, each having its own president and secretary. The sixteenth section will represent legal medicine and toxicology.

Smallpox at Hackensack.—Smallpox has become epidemic here. On the advice of the State Board of Health the town has been isolated. Guards are posted in the suburbs and no one is allowed to leave or enter the town. Thirty-five cases are reported. The health officers have taken possession of the new town hall as a hospital.

London Health in 1901.—The year 1901 has been very healthy in London. The average death-rate, in a

population of over four and a half millions, was 17.4 per 1,000. The aggregate deaths were 79,601, which is 9,874 fewer than the average for the last ten years. During the first half year there were 7,438 fewer deaths than usual. The rate was above the average throughout November, due to deaths from diseases of the respiratory organs. This was the result of excessive changes in temperature, spells of cold weather being accompanied by fogs. The worst week's rate was 22.3, in November, and the best 13.7, in June.

Kalamazoo's Appendicitis Club.—The Kalamazoo Appendicitis Club is the name of a new organization formed in that city to give aid to the great number of persons now suffering from appendicitis. Its membership hopes also to protect itself against the expense incurred in doctors' fees and loss of time. Seven hundred persons have joined the association. All the money is held in reserve for members' use.

Smallpox in State Home.—One thousand inmates of the State Institution, for Feeble-Minded, at Lincoln, Ill., have been placed in quarantine, as the result of the discovery of a number of cases of smallpox at the institution by Dr. J. A. Egan, Secretary of the State Board of Health. The disease had been prevalent in certain wards of the institution for two weeks, but was being treated as chicken-pox by the attending physicians.

Obituary.—Dr. Frederick M. Barrows, one of the most widely-known and highly-respected residents of Clinton, N. Y., died at his home on Utica Street last week. About a year ago Dr. Barrows suffered a stroke of paralysis, and a few months ago he became totally blind. Dr. Barrows was born in Connecticut, October 6, 1826. When he was four months old his parents moved to Decatur, Otsego County, N. Y., where he lived until he was twelve years old. In 1835 the family came to Clinton, where he since resided. He attended the Clinton Grammar School and entered Hamilton College, but left it during his sophomore year on account of ill health. Then he went to Geneva Medical College, where he was a fellow student with Dr. Walter Griswold and graduated in 1846. He has practised his profession at Clinton ever since, with the exception of one year, when he lived at Bridgewater. He was engaged in general practice and attended patients in all directions within a radius of ten miles from Clinton. He was a member of the Oneida County Medical Society. Dr. Barrows was a man of scholarly tastes and refined manners. He was imbued with the true appreciation of the duties of a physician and practised the healing art as one who finds his highest gratification that he can relieve suffering humanity rather than from a sordid sense of gain. He was a man of most pleasing address and made friends with all whom he met. His life in Clinton had been long and very useful, and his death will be mourned by the many whom he had helped and befriended. He was a man whom every one loved and honored, and in his death Clinton loses one of its most upright and noble characters. He was a loyal friend, a loving father and a tender husband. During the past two years death has entered his family several times, removing loved ones, but he always bore his trials with the Christian fortitude which has always characterized his whole life. The news of his death will be read with profound sorrow by the entire community. Dr. Barrows was married in 1846 to Lydia Dinsmore, who survives him. He leaves a son, Dr. Frederick E. Barrows, who came to Clinton a year ago to assume his father's practice.

Dr. William Augustus Pierrepont died of heart trouble at his late home, Brooklyn, N. Y., January 5th. Dr. Pierrepont was born in Brooklyn and was forty-six years old. After a preparatory education he studied law at Columbia University, receiving a degree in 1876. He did not practise law, but took a course in medicine at the University of the City of New York, being graduated in 1882. The following year he became resident physician and surgeon of the Brooklyn Hospital, where he remained for two years. After that he practised with Dr. Jasper Griswold in Manhattan.

RARE BONE DISEASES: OSTEOGENESIS IMPERFECTA, SENILE OSTEOMALACIA — OSTITIS DEFORMANS — OSTEOPLASTIC CARCINOSIS SECONDARY TO PRIMARY CARCINOMA OF THE PROSTATE—AMPUTATION FOR WIDESPREAD ABSCESSES—THE DISEASE OF BANTI.

THE recent meetings of the German societies have been interesting. These topics were the chief discussed. Lange, as guest at Gesellschaft für Natur-und Heilkunde zu Dresden (Muench. med. Woch., 1901, No. 45) gave a minute report of several autopsies on patients afflicted with bone diseases. The first was a case of osteogenesis imperfecta. The subject was a male child born prematurely of a physically well-developed primipara. It possessed a good layer of body fat and high-grade quantitatively-deficient development of the whole skeleton with a qualitatively-normal formation of bone. Microscopically there was no softening within the endochondral ossification; the bony vault of the skull was not macroscopically examined. There were multiple fractures of the ribs and long bones of the extremities which for the most part presented some effort at healing and redundant formations of callus. On account of these fractures there were very prominent shortenings and deformities in the lower extremities. Infractions were also common.

The second case was one of senile osteomalacia. The patient was a working-woman, seventy-six years old, the mother of thirteen children, admitted to the hospital July 24, 1900, on account of rheumatic pains in the arms and legs and universal high-grade marasmus. When a child she had rachitis. Her death occurred on March 8, 1901, in the presence of symptoms of general marasmus. The features of the autopsy were the following: Brown atrophy of heart; chronic bronchitis; edema of the lungs; atrophy of all tne organs of the abdomen; osteomalacia of the whole skeleton, showing microscopically widespread bony spaces and macroscopically universal atrophy with abnormal softness of the bone. The spinal column showed kyphoscoliosis toward the right in the dorsal region, with compensation toward the left and with lordosis in the lumbar region. The thorax was of irregular form on account of numerous infractions of the ribs. The pelvis was of typical heart shape, with the sacrum bent almost at right angles, with the acetabula pointed forward and the ilia faced outward and overhanging to an abnormal degree. The hip- and shoulder-joints showed arthritis deformans with numerous soft nodular enlargements of the bone about the joint. In addition to this there were scattered areas of new bone formation in the bodies of the vertebræ and in the malleoli.

The third specimen was one of ostitis deformans in a widow sixty-eight years old, born and bred in Dresden, admitted November 26, 1896, with the diagnosis of insanity secondary to multiple alcoholic neuritis. She had had three children and many miscarriages. There had been chronic swelling of the feet for many

years and severe cramps in the extremities. The examination presented fat, soft muscles, bowed tibiæ, and a broad angular forehead. Voluntary motion was very limited, with pain, tenderness and uncertain coordination. She died on August 18th with symptoms of increasing heart-failure and very marked edema of the lungs. In the interval no particular symptoms had occurred. Some time before death her forehead was noticed to be progressively more prominent. At the autopsy there were found the following features: Atrophy of the brain; degeneration of all heart muscles; universal sclerosis of arteries; chronic inflammation of the trachea and bronchi; long-standing congestion of the spleen, liver and kidneys; chronic catarrh of the stomach; scars of gummata in the liver; thickening of the duodenum; ostitis deformans of the whole skeleton. The skull in particular was of irregular thickness in the right frontal bone and in the occiput it had increased to almost two c.m. in thickness and consisted throughout of finely-porous, rather soft bone substance. The fossæ of the cranial cavity were rather flat, the face showed no changes. The vertebral column particularly in the thoracic and lumbar regions together with the sternum showed exactly the same changes. The right humerus contained in the upper third a marked bend, and in this region there was an evident narrowing of the medulla owing to the presence of the finely-porous bone substance in the bone. In the rest of the shaft there were areas of new bone formations. The pelvis was heavy and thick, normal in form except for a tendency to heart shape, the ilia and pubes were very much thickened in cross section their condition was the same as that of the vertebra. The femora showed a curve and thickening toward the front, just below the great trochanter. Here, as in the humerus, was a narrowing of the medulla caused by the presence of the new bone substance. The tibiæ were also curved to the front, irregularly thickening and in the same general condition as the other long bones. The fourth patient had suffered from osteoplastic carcinosis after a primary carcinoma of the prostate. He was also a laborer, sixty-two years old, admitted February 2, 1900, for chronic rheumatism. His history stated that he had never been seriously sick except for the rheumatism which began in 1899, at first in the left then in the right leg and finally becoming general. He was of medium weight, poorly nourished, heavy boned and weak muscled. He died June 23 after some pain and general wasting away. The autopsy showed the following: Brown atrophy of the heart; general hardening of the arteries of the right and left hydrothorax; atelectasis by compression of the lower lobes of both lungs; atrophy of the spleen, liver and kidneys; a new growth at the upper pole of the left kidney in the adrenal gland; primary carcinoma of the prostate; osteoplastic carcinoma of the whole skeleton. The prostate gland was slightly enlarged, hardened, irregularly deformed and not easily distinguishable from the surrounding organs. Sections showed a grayish-white homogeneous mass with a few lighter spots here and there; with the microscope a small-cell infiltrating carcinoma was seen. The cranium was asymmetrical, of irregular thickness, and increased weight. In both frontal bones, in one temporal bone, and in the occiput there were distinct, discrete, grayish-yellow flat bony new growths which for the most part penetrated the whole thickness of the skull. In the interior they were at times diffuse and at times circumscribed masses. In the ribs and sternum there were increased thickness and weight, with most of the spongy and compact bone displaced by a large, hard, gray-white osseous carcinoma. The vertebræ were very heavy and unchanged in form, but the interior of each was invaded by the same type of neoplasm. The pelvis was of the usual form, but the bones were everywhere thickened definitely or in nodes, especially in the ilia and descending rami of the pubes. All of these thickenings were made up of this same gray-white cancerous mass, or of a diffuse, irregular new bone substance. The femora were increased in weight. In the upper part of the neck and just below the great trochanter were new growths of bone the thickness of the finger. In the upper part of the medulla on both sides was the same gray-white tumor, cancerous in nature, in multiple deposits, each about the size of a hazel-nut.

Von Bergmann, at the Berliner medicinische Gesellschaft, October 30, 1901, read a paper on the amputation of the extremities for widespread progressive abscesses. Contrary to the contention of Virchow that the blood can hardly be a permanent bearer of the bacteriological products of disease, it is to-day established that the penetration of bacteria and their products into the blood and their continued growth there are not only possible but well-established facts. Furthermore, when such a condition of the blood exists, the prognosis in any case is most unfavorable. The good results which have been obtained in such cases of blood infection secondary to phlegmon have been described by Virchow in a Festschrift in honor of the seventieth birthday of Von Coler. The methods of treatment therein described were wide, free and numerous incisions. Occasionally, however, this procedure does not bring about the desired result, and the more radical step of amputation may be necessary. The dictum that has been so freely accepted which teaches that, when the blood has been found to contain the same bacteria as does the phlegmon, the surgeon should then withhold all treatment has been disproved. Recently Dörfler has shown that oftentimes in such cases prompt amputation will lead to a cure. Such treatment seems not only justifiable, but in point of fact the only available thing to be done. The rule by which amputations must be decided upon or avoided depends simply upon the reaction of the abscess under the treatment of free incisions. If the process still continues without abatement, whether the blood does or does not contain the bacteria, amputation should be done forthwith and as high above the phlegmon as possible. Dörfler gives several illustrative cases which his assistant has presented for him. In a series of these cases five show pure cultures of the same bacteria as were in the phlegmon and yet the results were good. The best example is the following case: A student, twenty years old, in alighting from a horse, fell against a passing beer-wagon, injuring his hand. He was immediately taken to the hospital, where two days later his finger was amputated. In spite of this, however, the phlegmon progressed rapidly. Examination of blood taken from a vein on the opposite side of the body was positive, showing numerous streptococci. Wide, free and numerous incisions were made in the diseased member, but without effect upon the infection. Repeated examinations of the blood gave the same results and on the same night amputation of the arm was undertaken. Improvement immediately set in and cure resulted. The most interesting fact in the case is that twice a day for a number of days after the operation streptococci were present in the blood in steadily-decreasing numbers. Fourteen days after the accident they were absent, but on the same day they were found in pure culture in pus from the wound. The man is now

perfectly well and owes his life to that early amputation.

SENATOR presented a paper on the disease of Banti, who described a disease with the symptoms of profound anemia—very great enlargement of the spleen, late appearing tumor of the liver, and ascites. In Italy it is known as Banti's disease. In German literature as yet no notice has been taken of it. It is an interesting fact that this is no new disease. Banti has simply collected in scientific relation a thorough description of a large number of diverse and varying clinical features. He distinguished three stages, as follows: (1) Initial stage, anemia with progressive enlargement of the spleen with a duration of from three to five months; (2) transitional stage, with decrease in the urine, abundant urates, urobilin, and later coloring matter from the bile; duration a few months; (3) final stage, with ascites and tumor of the liver, increasing anemia, slight increment in the white blood-cells, and death after from five to twelve months. The whole disease lasts about six years, occasionally twelve years. If one studies these stages one will find that the first has long been known under the name of primary idiopathic enlargement of the spleen, or splenomegalia. Other names for it are pseudoleucemia (Conheim), and anemia splenica (Griesinger). The later stages are practically those of cirrhosis of the liver with ascites, although some of its features differ slightly from that disease. Banti regards the spleen as the primary and the liver as the secondary seat, because the latter is usually smaller than the spleen. His proof lies in the pathological condition of the spleen, namely, a highly-developed atheroma of the splenic vein, and in the results of treatment. This view of a primary disease of the spleen must be accepted. The cause of the whole disease is an infection or intoxication through the intestinal canal. The ascites may not be in consequence of the cirrhosis of the liver because it is for the most part immaterial and does not increase with the disease of the liver and may disappear through treatment. In the third stage active bleeding through the nose and the intestinal canal is characteristic. During it Banti has found the blood in the condition of simple anemia. Senator has found a disproportionate decrease in the hemoglobin and in three cases a progressive decrease in the number of leucocytes—in other words, a leucopenia. Perhaps this may be characteristic of Banti's disease as an entity. In the marrow of the bones are evidences of profound anemia. Senator then discussed the differential diagnosis between this disease and pseudoleucemia by the increase of lymphocytes, from malaria by the plasmodia, from cirrhosis of the liver by the history and signs, etc. It is possible that this affection is a link between anemia and leucemia. The prognosis is always unfavorable. Removal of the spleen seems to be the only treatment. Eleven cases have been operated on and reported by Maragliano. Only two died and they of hemorrhage. It is very desirable that further data concerning this curious disease should be collected.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held December 17, 1901.

E. Franklin Smith, M.D., Chairman.

Pernicious Anemia.—Dr. James J. Walsh detailed the history of a case of pernicious anemia, with special reference to the etiology suggested by Dr. William Hunter of London, in which gastro-intestinal sepsis is considered the principal causative influence in the disease. Dr. Hunter found that in a series of pernicious anemia cases practically all of the patients suffered from very bad teeth. Usually the teeth did not give very much pain, but were discolored and were evidently the seat of extensive bacterial growth in their carious cavities. The swallowing of these micro-organisms in large numbers, Dr. Hunter thinks, causes deterioration of digestion and finally leads to gastric sepsis. This observation of Dr. Hunter's has not been confirmed by other clinicians, who have been especially watchful with regard to the condition of the teeth in these cases, since Dr. Hunter's publication. Dr. Osler of Baltimore reported, through his assistant, at the last meeting of the American Medical Association, that in the cases of pernicious anemia under his care many of the patients presented bad mouth conditions, but these conditions were not worse than those that occur in ordinary hospital patients suffering from other diseases. English observers have also expressed the opinion that oral conditions were not of as serious etiological importance as Dr. Hunter considers. In New York dentists consulted with regard to the matter expressed the opinion that the bad teeth so common in pernicious anemia were rather an effect than a cause of the disease. The lowered state of the patient's nutrition reduces the resistive vitality of the dental structures and so permits of a more rapid decay.

Antistreptococcus Serum.—Dr. Hunter reported three cases in which antistreptococcus serum was used with very satisfactory results for the treatment of pernicious anemia. The theory of the employment of this remedy is that streptococci are the most virulent micro-organisms that occur in the mouth and consequently the most important in the production of the gastric septic condition. In three cases the use of antistreptococcus serum seemed to produce a remission of the symptoms of pernicious anemia that lasted as long as the patients were under observation.

Case without Oral Infection.—Dr. Walsh's patient was a young woman who had always been extremely careful in the matter of personal cleanliness, so much so that she was considered somewhat of a crank. Her teeth and mouth had always been a source of special attention and they were as clean and sweet as possible notwithstanding the many months during which she had suffered from serious stomachic disturbances. Gastric disturbance was so complete that she retained very little food and growing weakness, the result of inanition, was a marked feature of the disease. As this severe disturbance of the stomach is attributed by Dr. Hunter to some form of gastric sepsis, notwithstanding the presence of good teeth in this case, it was considered advisable, as other remedies failed to bring any lasting relief, to try antistreptoccic serum. Six injections at intervals of three days were given. At the first injection about one-half the dose of serum supplied by the Board of Health of New York was used. There was no local or general reaction. Three days later the full contents of an ordinary Board of Health phial of the serum were employed. This produced a slight local reaction in the shape of a patch of urticaria with some erythema around the point of injection. The third dose produced considerable urticaria over even distant parts of the body. The remaining doses were all of them followed by this discomforting urticaria. There was slight fever, but this was attributed rather to the restlessness produced by the skin eruption than to febrile reaction from the serum.

Therapeutic Effects.—As far as could be seen, absolutely no benefit accrued from the use of the serum

injections. The patient had improved for some time before their employment under the use of nux vomica and arsenic. Vomiting spells, however, had been recurring occasionally and it was in the hope of allaying these that the serum was used. Toward the end of the serum treatment vomiting became more frequent and about a month after the last injection the patient died. As advised by Dr. Hunter, internal antiseptics, salol and salicylate of bismuth and occasional divided doses of calomel were employed. These seemed to relieve the tendency to diarrhea that occasionally became a marked feature of the affection. Arsenic, however, used as Fowler's solution seemed to do more good than any other remedy.

Failure of Antistreptococcus Serum.—In conclusion Dr. Walsh said that the use of antistreptococcus serum had proved a failure in every disease in which it had been thought possible that it might do good. The reason for this is not far to seek. Under the form streptococcus, it is clear to bacteriologists that a large number of different kinds of micro-organisms are grouped. It is practically impossible to obtain the specific serum opposed to any definite group of streptococci, since we do not know any individualizing characteristics of the different forms.

Probability of Failure.—Dr. Alfred Meyer said that while Dr. Hunter's report had very naturally aroused interest because it offered a hopeful remedy in what had been a hopeless disease, disappointment with regard to the use of antistreptococcus serum in other affections might have led us to anticipate disappointment in this. So far we have no remedy capable of putting an end to the progress of pernicious anemia, though the disease is liable to remissions that have given many remedies a reputation for producing some therapeutic effect.

Causes of Epilepsy.—Dr. Louise G. Robinovitch read a paper involving some clinical considerations of the genesis of epilepsy. The paper was the result of the study of a large series of epileptic cases in the Asile St. Anne in Paris during the last few years. Under the direction of Dr. Magnan of that institution Dr. Robinovitch had special opportunities for the collection of data with regard to the etiological factors in the history of the epileptic patients who are sent to this institution as well as the insane. In the majority of the cases of epilepsy a history of alcoholism in some of the progenitors of the patient could be obtained. Epilepsy in the descendants may be the direct effect of alcoholism in the preceding generation. The mental deterioration may, however, skip a generation and not appear until the grandchildren of the alcoholic individual. Epilepsy is associated with insanity in this matter and alcoholism seems to have a special influence in causing deterioration of the mental condition. The alcoholic influence was not necessarily present in the direct relatives of the epileptic. At times it would seem as though the direct influence of alcohol is so far back in the family history that it can not be traced. In many of these cases, alcoholic tendencies in collateral branches of the family, in uncles or aunts, serve to show the unstable mental condition of the race.

Statistics of Alcoholism.—In 140 cases of epilepsy in which the history was very carefully followed up over 90 cases proved to have traces of alcoholism in the immediate ancestry. This is over 63 per cent. and shows what an enormous influence in the production of this form of mental disease the consumption of alcoholic intoxicants has. Alcohol, as is well known from statistics, increases the birth-rate but greatly increases the death-rate in countries where it is freely used. Children of alcoholic parents are especially liable to die young. Something of this early fatality is due to the fact that such children are prone to be neglected; but still more of the infantile mortality is due to the disturbed nervous system that is transmitted from alcoholic progenitors. The use of alcohol to excess produces epileptiform convulsions. These are not true epileptic seizures. The instability of nervous system which such seizures indicate leads, however, to the occurrence of epilepsy in the descendants. Other direct causes of epilepsy have been mentioned, for instance, the acute infectious fevers during pregnancy or the occurrence of acute infection in the children themselves. Such accidents, however, are very much more frequent than is epilepsy. Some predisposition is necessary before epilepsy occurs. This predisposition is due to the deteriorated nervous system transmitted by alcoholic parents.

Alcoholism and Epilepsy in America.—Dr. W. C. Hollopeter of Philadelphia in discussing Dr. Robinovitch's paper said that he was firmly persuaded of the influence of alcoholism in the production of epilepsy. He has a professional friend whose brothers are epileptic and who is firmly of the opinion that the epileptic seizures are due to the alcoholic history in the family. Alcoholism, however, produces a predisposition not only to epilepsy, but also to other nervous manifestations. Feeble-minded children are especially liable to occur in families with a history of alcoholism. Many of the extremely neurotic children that are seen so frequently nowadays will be found to have alcoholic progenitors.

Dr. Bell of Englewood, New Jersey, said that in cases where several children in the family present neurotic manifestations, he is accustomed to look for a history of alcoholism. He has under his care a family of seven children, most of whom present some serious nervous condition, whose father was a confirmed dipsomaniac. In another case out of a family of six children there is but one perfectly normal child, and the cause of the neurotic conditions present in the others seems to be the family predisposition caused by ancestral alcoholism.

Malarial Poisoning and Epilepsy.—Dr. Bell recently saw a case in which a family history of alcoholism could be absolutely excluded. The patient after a severe attack of malaria developed her first epileptic attack at the age of about four years. The family had been living in New Jersey, but moved away in order to get rid of malaria. After the removal the child had a series of what were called congestive chills and later developed epileptiform convulsions. These continued for a couple of years at irregular intervals and then disappeared for a time. At twelve the patient menstruated and had an attack of epilepsy just before and at the conclusion of her menstrual period, the interval being about four days. This recurred each month for several years. When she was about sixteen, one of her ovaries was removed because of cystic degeneration. For three months after this the patient was well. Then her epilepsy developed again and a distinguished ophthalmologist found that her eyes needed surgical care. A tenotomy was performed and for several months no epileptic attacks occurred. After this period, however, the epilepsy reassumed its sway and the patient continues to have her attacks at each menstrual epoch. The direct cause of these attacks would seem to be some serious disturbance of the nervous system produced by the malarial poison.

Epilepsy and Infantile Eclampsia.—Dr. Berg said that the attribution of the epithet alcoholic to a parent is very easily done, but may not be entirely justified if the details of the case are followed. Dr. Robinovitch claims that in France the use of more than two liters

of wine constitutes alcoholism. Of the ordinary French table wine this would be equivalent to about three liters of beer, that is to say six to eight glasses. There are many workmen in this country who take this amount of beer and yet can by no means be considered to be alcoholics. If this quantity were taken as a standard it would seem easy to find even a greater proportion of parental alcoholism in cases of epilepsy than are exhibited in the statistics presented by the reader of the paper. There is no need to take so far-fetched an etiological factor as alcoholism for epilepsy when we consider how important the occurrence of infantile convulsions is for disturbance of the child's nervous system. Long ago Dr. Seguin taught that all epileptics will be found to have a history of having suffered from eclamptic convulsions in childhood. Epilepsy and eclampsia are nearly of the same character. Epilepsy is really a chronic eclampsia that occurs without immediate cause. The occurrence of a convulsion in childhood, when the nervous system is especially subject to deteriorating influences, gives a special tendency to the occurrence of similar convulsions later on in life if some cause proves sufficient to reawaken the once aroused convulsive center. In a patient that recently came under Dr. Berg's care, the immediate cause of the epileptic seizure was the eating of a plate of veal. The patient was a young college student, who had no memory of ever having had epileptic seizures. His mother, however, recalls the fact that he had a convulsive attack when about two years of age. Notwithstanding the employment of bromides very liberally, he continued to have epileptic convulsions every two or three weeks for several years. It was only when thoroughly brominized that he finally got rid of them.

Standard of Alcoholism.—In closing the discussion Dr. Robinovitch said that the amount, two liters of wine, as the criterion of alcoholism had been established by well-known medical authorities who thoroughly understood both the qualities of their wines and of the French people. It is probable that different standards would be required for different people. For phlegmatic Germans the consumption of the equivalent of this amount of alcohol might not constitute alcoholism; for excitable Frenchmen, however, it means an irritation of the nervous system that must surely prove serious in the long run. It is well known that practically only the children of neurotic parents, or those who are for some reason predisposed to nervous phenomena, are liable to infantile convulsions. In some children a very slight cause is sufficient to bring on a convulsion. In certain families the infectious fevers are always ushered in by a convulsion instead of a chill. This indicates the family predisposition to instability of the nervous system. Careful search of the family history will show that the cause of this predisposition in most cases is alcoholic heredity. Where eclamptic seizures have occurred in childhood it is easy to understand that epilepsy may occur later in life, because the predisposition to these explosions in the nervous system is already present. This does not prove, however, that the convulsion in childhood is the cause but on the contrary serves to show how much the predisposition to nervous manifestations has to do with the earlier and the later seizures. With regard to Dr. Bell's case in which there seemed to be no cause for the epilepsy except malarial poison, Dr. Bell said that the family history with regard to epilepsy was negative. He mentioned, however, that the uncle of the patient had suffered from epileptic seizures after an injury which caused depressed fracture of the skull. Depressed fractures of the skull are only rarely followed by epilepsy and the fact that attacks occurred in this case would seem to point to the existence of a family predisposition to epilepsy. Such histories are often spoken of as negative, when rational examination of them will point out the significance of the tales that are often passed over without due appreciation of their importance.

SYMPOSIUM ON CIRRHOSIS OF THE LIVER.

The following papers were read: Etiology and Pathology of Cirrhosis of the Liver by Dr. James K. Crook; Cirrhosis of the Liver in Children by Dr. W. C. Hollopeter of Philadelphia; Treatment of Cirrhosis of the Liver by Dr. George M. Converse. They will appear in subsequent issues of the MEDICAL NEWS.

Infantile Hepatic Cirrhosis.—Dr. Berg in the discussion of the papers said that very few cases of cirrhosis of the liver came under observation at Mt. Sinai Hospital. Among children in whom Dr. Berg had been especially interested atrophic cirrhosis of the liver had never been noticed. All cases of children's disease admitted to the hospital are carefully examined and the size of the patient's liver is noted, so that it seems improbable that the condition would be passed over. Large livers are common enough in children. These do not seem ever to be true hypertrophic cirrhosis, but rather congestive enlargements of the liver. Dr. Berg thinks that it is a mistake to talk of cirrhosis of the liver in general, meaning thereby both the hypertrophic and the atrophic form of the disease. Hypertrophic and atrophic cirrhosis are very different conditions and should be kept absolutely separate. The term cirrhosis should be limited to sclerotic conditions only. It is this form of cirrhosis, especially when accompanied by dropsy and enlarged veins, that Dr. Berg has never seen in children. The diagnosis of hepatic cirrhosis should never be made while there is fluid in the abdominal cavity. Dr. Berg had this impressed upon him very strongly some time ago in a case in which all the indications seemed to point to the existence of hepatic cirrhosis. After the removal of the abdominal fluid the condition was found to be due to cancer of the stomach pressing upon the portal vein. This had caused not only ascites and hemorrhoids, but had given rise also to the formation of veins upon the abdomen in the form of a typical caput medusæ. The liver proved to be perfectly normal. Any closure of the portal vein may give rise to ascites, and yet this condition is, of course, almost impossible of diagnosis. But after the removal of the fluid from the abdomen the liver will be found to be normal and so the idea of cirrhosis will be given up.

Slow Removal of Fluid.—Dr. Alfred Mayer said that, following the example of a colleague who made the suggestion some twelve or fourteen years ago, he employs a very small cannula for the removal of ascitic fluid instead of the usual large cannula. The removal of the fluid from the abdomen in a short time, something less than an hour, as is usually done, leads to its rapid reaccumulation. The small trocar is allowed to remain in the abdomen and the patient is surrounded by bandage material to absorb the fluid which gradually finds its way out through the small opening in the cannula. Although the evacuation of the ascitic fluid by this slow method is followed much less frequently by its reaccumulation, there are certain objections that have been urged against it. At times the fluid does reappear. Then, the fact that the patient is compelled to lie for several days in wet bandages is considered a serious objection by some. Eczematous conditions of the skin may result from this. Some fear the effect of the cannula upon the intestines. If the instrument has a smooth round end there seems to be no danger, however, of its doing any serious damage.

Premature Evacuation.—Dr. James J. Walsh said that it seems advisable not to evacuate the ascitic fluid before it has begun to exert some pressure upon the abdominal wall. The hope of ultimate relief in these cases is the formation of a large collateral venous circulation in the abdominal walls. This will only form under the influence of considerable pressure within the abdomen. The ascitic fluid, then, should not be evacuated before some pressure symptoms are noted. This is especially true in cases where some dilatation of veins in the abdominal wall is already noted.

Dr. Walsh said that it would be a mistake to think of cirrhosis only or even mainly in connection with alcoholism. Many theories have been advanced involving other toxic agents besides alcohol. It is well known that certain of the mineral poisons, especially lead, can produce cirrhosis of the liver. Copper and mercury undoubtedly also induce hepatic sclerosis very similar to ordinary cirhosis. At the last meeting of the American Medical Association, Professor Vaughan of Ann Arbor called attention to the fact that aluminium seems to be one of the substances which can produce cirrhosis of the liver. As alum is very commonly used in the cheaper grades of baking-powder, this fact should be borne in mind by those who see cases of cirrhosis of the liver in which there is no alcoholic history.

Terminology of Cirrhosis.—In closing the discussion Dr. Crooks said that the terminology of the subject of cirrhosis is all liable to misconception. Cirrhosis itself is a misnomer. Laennec used the word originally to indicate the fawn color of the hard livers which he had observed. Atrophic cirrhosis, of course, should be called chronic interstitial hepatitis. Atrophic cirrhosis is at the beginning hypertrophic cirrhosis. Only the biliary hypertrophic cirrhosis is independent. With this confusion of terms it is impossible to make nice distinctions without misunderstanding.

Dr. Hollopeter said that he had been stimulated to study cirrhosis in children by the English observations. He had seen some cases with Dawson Williams in London last June and undoubtedly there is more of it in this country than is generally supposed.

BOOK REVIEWS.

Electricity in Medicine and Surgery, including the X-Ray. By William Harvey King, M.D. With a Section on Electro-Physiology by W. Y. Cowl, M.D., of Berlin, and a Section on the Bottini Operation by Albert Freudenberg, M.D., of Berlin. Boericke & Runyon Co., New York.

For a long time need has been felt for a concise, terse, complete and modernized work on the subject of electro-therapeutics, yet one which the busy practitioner, not overfamiliar with electro-physics, can read and understand.

Such a book has been written by Dr. King, and, while the electro-specialist unquestionably goes into his subject somewhat more deeply than does the author, it will prove to be of great value to the non-expert, written as it is in an easy, fluent way, and in a manner comprehensible to the novice.

The work, as is customary, treats first of electro-physics (without a knowledge of which electro-therapeutics must ever prove unsatisfactory), followed by a chapter each on the X-ray, motor-points, electro-diagnosis and organic electrology.

Part III., on electro-therapeutics, is subdivided into nine sections, each of which gives a good description of the use of electricity in a different branch of practice, with the choice and strength of current, electrodes, etc., and their application. These are copiously illustrated by drawings and diagrams that, unlike many of their kind, really do illustrate the point to be considered.

Where there are two or more opinions held by authorities on a given subject, both are plainly stated and the reasons for them, thus leaving the reader cognizant with the main facts of each, and capable of an intelligent choice of methods. Coupled with these are the opinions and experiences of the writer and his results.

So many claims of an extravagant nature have heretofore been made for electricity that its trial and failure in certain conditions have had a tendency to bring its employment into the category of unsatisfactory methods. But the fact still remains that it has an important place in modern practice, and its proper application to suitable conditions and cases cannot be denied. That it will ever supplant medicine or surgery in many things is not to be expected, and any such idea would be absurd; that it will greatly aid them, and in some conditions will prove more satisfactory is true; and in this book, the author has endeavored to frankly state his opinions and reasons for them.

The book is handsomely and substantially bound, clearly and well printed from good type on excellent paper, having wide margins, and is of a convenient size and form for holding in the lap. A careful study of its contents cannot fail to give the reader, be he specialist or general practitioner, many points of value to him, and to post him in the important advances of that branch of science, without trying to impress him as to its infallibility.

A Treatise on Pharmacy. By Charles Caspari, Jr., Ph.G., Professor of the Theory and Practice of Pharmacy in the Maryland College of Pharmacy. Second Edition. Lea Brothers & Co., Philadelphia and New York.

Former works in pharmacy have consisted of descriptions of pharmaceutical processes and a résumé of the official preparations in groups according to the classes to which they belong. Professor Caspari treats these sections in a concise and practical manner, but in addition endeavors to give helpful suggestions about every step in the various processes of manufacture. Should an unlooked for color or precipitate appear in a galenical, here will be found the explanation, and, if there be such, the remedy. The author does not recognize the pharmaceutical percentage solution in which solids are weighed and liquids measured, although the Pharmacopœia adopts this idea as being the only practical basis for bedside measurements. In this useful book we should like to see a chapter on "incompatibles" and full treatment of the most used unofficial preparations. The illustrations are numerous and add much to the value of the work.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Anatomy in Its Relation to Art. By Dr. George McClellan. Quarto. 140 pages. Illustrated. W. B. Saunders & Co., Philadelphia and London.

A Text-Book on Diseases of the Ear, Nose and Throat. By Drs. Chas. H. Burnett, E. Fletcher Ingals and James E. Newcomb. 8vo, 716 pages. Illustrated. J. B. Lippincott Company, Philadelphia and London.

A Text-Book of Surgery. By Dr. Hermann Tillmanns. Translated from Seventh German Edition by Drs. B. T. Tilton and J. Rogers. Edited by Dr. L. A. Stimson. Vol. I. 8vo, 841 pages. Illustrated. D. Appleton & Company, New York.

CONGENITAL ATRESIA AND STENOSIS OF THE RECTUM AND ANUS.

BY W. REYNOLDS WILSON, M.D.,
OF PHILADELPHIA.

FAULTY development of the rectum and anus occurs as an infrequent malformation in the newborn, the proportion being one instance among 10,000 infants. The gravity of the condition depends upon the character of the malformation and the opportunity for treatment.

The classification of the anatomical conditions may be simplified, after differentiating atresia and stenosis, by accepting Ziegler's classification of the former, as follows: (1) Atresia ani simplex; (2) vesicalis; (3) urethralis; (4) vaginalis. This classification includes certain sub-varieties; for instance, in simple atresia the rectum may end at a variable distance from the anus; secondly, the formation of the anus may vary from that of the normal to total absence of the anal depression; again, the more or less complete obliteration of the rectal tube at its distal extremity may simulate a complete absence of the rectum.

As to the deviation of the rectum admitting of such conditions as are included in atresia vesicalis, urethralis, vaginalis, we may differentiate the conditions according to the sex of the infant. In the male, the fistulous opening connecting with the rectum may appear upon the scrotum, upon the inferior surface of the penis, and in some instances may connect with the urethra. In the female, the opening may appear in the vulvar fourchette in advance of the hymen or it may find entrance into the vagina proper. In either sex the rectum may enter the bladder or the ureter.

In the development of the rectum in the embryo the entoderm, which serves as the lining membrane of the gut, may undergo imperfect differentiation, resulting in an incomplete formation of the canal. In consequence of such interruption in development we have a condition of stenosis. Trélat emphasizes the existence of transverse folds shutting off the rectum and causing dilatation above the point of stenosis. He regards such a condition as probably an exaggeration of the rectal valves. Simple stenosis of the anus may exist without associated stenosis of the rectum.

Pathogenesis.—Malformations of the rectum and anus are to be interpreted, according to Forgue, either as instances of reversion in normal development, giving rise to permanent conditions of deformity, or as instances of aberrant development. Certain embryological data may be considered in this connection.

In the earliest stage of embryonic life the germinal area becomes separated into an anterior or posterior zone. The former comprises the three leaflets of the blastoderm which enter into the formation of the neural canal and notochord; the latter, which includes the primitive streak, becomes thinned as it approaches the caudal area of the embryo, constituting ultimately a twofold membrane composed solely of the ectoderm and entoderm, the so-called anal membrane. This membrane is situated in the dorsal aspect of the embryo in the median line, but as the embryo increases in its longitudinal axis and becomes bent upon its ventral surface the anal membrane, which is now designated the anal plate, becomes directed toward the center of the general embryonic cavity. In the meantime the caudal tubercle formed by the caudal projection of the blastodermic elements of the primitive streak surmounting the anal plate furnishes the protone of the future pelvis.

By the fifth week of embryonic life a depression of the anal plate occurs by invagination of the ectoderm, resulting in a small fossa. This is called the proctodeum. In vertebrates the proctodeum does not correspond to the end of the intestine, inasmuch as the gut extends beyond the position of the future anus. Ultimately, however, this post-anal region of the intestine disappears.

Previous to the folding forward of the posterior extremity of the germinal area resulting in the anal membrane, there occurs at this extremity of the embryo a slight outward bulging of the entoderm. As the posterior extremity of the embryo turns forward this beginning diverticulum, the allantois, assumes a position between the anal region and the umbilical vesicle. The allantois communicates with the posterior extremity of the mesenteron, or primitive gut, which hitherto has terminated in a blind extremity, and the common receptacle thus formed constitutes the cloaca. This general cavity becomes divided into the genito-urinary sinus, which serves as the common termination of the genito-urinary system, of the intestinal canal, and of the cloaca proper. The cloaca therefore is in direct communication with the genito-urinary sinus on the one hand, while on the other it is separated from the amniotic cavity by the anal plate. The intra-embryonic portion of the allantois, by reason of the division which takes place progressively between the genito-urinary sinus and the cloaca, gradually loses its communication with the latter. This division is effected by the coalescence of lateral folds of the mesodermic layer which unite from above downward in the median line. The genito-urinary and rectal canals are thus made separate. This division is complete, according to Minot, at the fourteenth week. The anal depression shares in this division,

and at about the tenth week the proctodeum is separated from the future orifice of the urogenital sinus by a circumvallate fold of ectoderm which surrounds the area that is later to become the anus. The newly-formed septum finally develops into the pyramidal mass of tissue which constitutes the perineum. The anus itself is formed by the appearance of small isolated areas of degeneration in the ectoderm, which later become confluent. By the extension inward of this process of tissue absorption the anal pit becomes deepened and the depression gradually approaches the end of the bowel. In the fourth month the anal membrane breaks down and disappears.

The walls of the anus gradually become more and more defined, and the epithelial layer which is continuous with the mucous membrane of the rectum makes its appearance. The deeper layer of the mesoderm becomes differentiated into the muscular and fibrous layers which constitute the underlying structures of the rectal tube.

Interruption in this process of development may affect either the rectum or the anus, resulting in, first, a failure in approximation of the rectal tube to the anal opening; second, a permanent vestige of the anal membrane which remains as an obstruction to the passage of the contents of the bowel; third, a deviation and abnormal anastomosis of the rectum with neighboring organs. Abnormalities in development may affect the anus and rectum coincidently or either structure alone may be the seat of malformation.

Description.—The conditions in stenosis call for no further classification than that dependent on the degree of narrowing. As to atresia of the rectum we may note that the arrest in development may involve a more or less extensive segment. Two types are observed. First, one in which the absence of the rectum may be partial. In this form of atresia the cul-de-sac which marks the termination of the gut may descend into the excavation of the pelvis and adhere by a fibrous tract (1) to the connective tissue lining the posterior part of the bony pelvis; (2) to the basfond of the bladder; (3) to the uterus or the vagina in the female. Second, total absence of the rectum may exist with extensive obliteration of the gut and attachment of the cul-de-sac to the bony pelvis at the level of the sacro-vertebral angle. In certain rare cases the absence of the rectum coincides with arrest in development of the colon. In either form of atresia the obliteration may exist simply as a muscular or fibrous cord, the most careful examination of which fails to reveal the presence of a canal, and in some instances even the strand of tissue which represents the vestige of the rectum may escape detection altogether. As to atresia of the anus we may note that the opening may be permeable only for a certain distance. The configuration of the anus in such cases is normal, but the opening will admit the finger or a sound only to a depth varying from a few millimeters to three or four centimeters. In total absence of the anus the skin may extend from one buttock to the other without a trace of any opening, even sometimes without a notable depression. In such cases abnormality in development of the pelvic region is shown sometimes by the nearness to one another of the tuberosities of the ischia.

Symptomatology and Diagnosis.—The evidences of stenosis and atresia depend upon the degree of malformation. Where the obstruction is absolute and the conformation of the anus abnormal the condition declares itself promptly. There is retention of meconium together with vomiting and abdominal distention. Among the less distinctive symptoms are anorexia, and restlessness alternating with periods of apathy. The child is apt to utter a continuous distressed cry in its restless moments. Hyperesthesia and fever are present. As the condition progresses the infant becomes more or less emaciated and the contrast between the hugely distended abdomen and emaciated portions of the body is sometimes marked. The surface gradually becomes cold and the skin assumes an earthy color, alternating sometimes with cyanosis and mottling. If the condition is not relieved death occurs in from four to six days.

In those cases in which the anus is pervious while the rectum remains the seat of atresia the condition may not be detected, and important symptoms diagnostic of obstruction may escape notice until the opportunity for treatment has been lost. Valuable time is often consumed by repeated attempts to relieve supposed constipation by enemata.

Should the rectum communicate with the genito-urinary tract the fecal material may find exit through this abnormal course. In such cases the vice of conformation may not be incompatible with existence during the early months of life. Communication between the rectum and bladder, however, offers an instance of false evacuation fraught with grave consequences, inasmuch as the fecal masses, which gradually become more and more consistent, act as a source of obstruction. Cystitis, infiltration of urine, and peritonitis are apt to supervene, followed by death.

As to the diagnosis of atresia the anatomical signs of its presence are usually unmistakable. Where a membranous obstruction exists the blind pouch corresponding to the distended rectum contains meconium, the presence of which may be detected by increased bulging during efforts of crying or straining on the part of the infant. Where the obstructing membrane is sufficiently thin the dark color of the meconium may be recognized. The collection of meconium is liable to diminution in bulk through the absorption of its fluid contents in cases in which evacuation is not established.

In atresia of the rectum without deformity of the anal opening the evidences of retention are recognized, first, by exploration of the anal depression with the finger or sound, notably during the efforts of crying, when the distended cul-de-sac may often be detected; second, by the absence of meconium upon the napkins of the infant;

third, by the general symptoms first described. In instances of atresia complicated by anastomosis of the rectum and the genito-urinary tract the condition is recognized by the absence of evacuation through the anus and by the presence of meconium in the urine. Local irritation due to the presence of meconium and the graver symptoms of obstruction of these passages are important factors in diagnosis.

There are but few conditions that might give rise to symptoms analogous to those dependent on stenosis and atresia. The meteorism of atresia is more extreme than distention due to any other cause. The rapidly progressive development of meteorism without inflammatory signs is also of importance. The only conditions that could possibly simulate the distention due to obstruction in the ano-rectal region are infantile peritonitis and distention of the bladder from retention. Further investigations of such conditions would render their diagnosis unmistakable. Intestinal obstruction proper is not accompanied by such sudden and marked meteorism.

The obstruction due to intussusception is at first accompanied by contraction of the abdominal muscles corresponding to the crises of intestinal peristalsis. In the intervals between such contractions the abdominal walls remain yielding, to such an extent as to admit of examination of the abdomen by palpation. The further evidences of obstruction in intestinal invagination, especially the passage of blood by the rectum, are entirely foreign to the signs of obstruction due to atresia.

Treatment.—The object of treatment is to establish the normal anatomical condition as far as possible. This is to be brought about by connecting the blind extremity of the gut with the anal depression. When such conditions exist as to make this impracticable an opening directly into the intestinal tract without regard to the anatomical relation of the rectum and anus becomes necessary. In most cases the indications for operation are urgent. The necessity for immediate intervention is not apt to exist in simple stenosis, nor in instances of deviation of the rectal canal without obstruction. In cases of imperforation, however, a means of exit for the intestinal discharges must be promptly established, otherwise the infant will perish from the results of obstruction.

As to the method of procedure we may note in reference to stenosis that gradual dilatation is indicated. The permanent retention within the rectum of a dilating staff in the form of a flexible bougie is neither necessary nor practical. The dilatation must be practised until the stenosis has been permanently overcome. It is to be noted further that in cases, alike of stenosis and of atresia, in which apparently marked deviation from the normal exists the sphincter muscles of the anus are frequently well developed. In cases of stenosis, therefore, after the original contraction may have been overcome, the spasm of the sphincters may give an exaggerated impression of resistance. The occasional administration of a mixture of castor-oil and glycerin to induce a partial laxness in the discharges is to be recommended; or, instead of this, rectal suppositories of glycerin, manufactured in elongated flexible form, may be introduced into the rectum daily. Rectal injections of saline solution by means of a woven silk catheter introduced to beyond the point of stenosis may be resorted to for the same purpose.

In deviation of the rectum with anastomosis with the bladder or urethra it may be necessary to relieve the obstruction. According to Ball the method of procedure in such case is to perform perineal section as a primary operation, entering the base of the bladder and opening thereby a means of rectal evacuation. Later the colon may be approached by inguinal colotomy, inasmuch as the rectum is held suspended in the pelvis by its attachment to the bladder, and is therefore out of reach by the perineal operation. In performing the secondary operation the cul-de-sac may be drawn up into the inguinal incision and, after its attachment to the edges of the abdominal opening, may be incised. An artificial opening is thus established similar to that in laparocolotomy, while at the same time the perineal incision may be encouraged to heal.

In most cases it will be necessary to postpone the second operation for some months—possibly until the child has entered its second year. At best the infant's vitality can scarcely survive these repeated operations. In view, therefore, of the necessity in many cases of early interference, and of the shock following operation at a time when least may be expected of the infant's powers of resistance, it is essential that the infant be nourished by the mother; if this is impracticable recourse should be had to a carefully modified milk food. The administration of whisky and the application of oil rubbings are important adjuncts in treatment. The most scrupulous care in the hygienic surroundings of the infant should be observed. In the interval in which perineal drainage is maintained frequent changing of the napkins, constant inspection in order to estimate the quantity of fecal matter discharged and to insure the permeability of the wound to the excretion of urine, as well as the cleansing and repacking of the wound, are essential.

Two methods of treatment in imperforation may be considered: (1) The opening of the rectum by perineal incision at the anal site; (2) the establishment of an intestinal outlet by means of inguinal colotomy after the method of Littré. Generally speaking, the inguinal incision is to be preferred when prompt relief is demanded. Where the cul-de-sac is accessible and where it can be drawn down to allow its artificial attachment to the inferior pelvic tissues the perineal operation may be undertaken, although the precise indications for its employment are not always present. It is contra-indicated where the termination of the gut is high, attached, for instance, in the neighborhood of the promontory, refusing to descend with the effort of crying and thus eluding the grasp.

The narrowness of the pelvis, characterized by the apposition of the tubera ischorium, is a proof of arrest in development of the pelvic tissues, the rectum included, and is sufficient contra-indication for the perineal operation.

Forgue bases the indications demanding perineal operation upon the condition of distention of the perineum, upon the descent of the rectum during the infant's cry, upon the actual presence of the anus and upon the detection of the cul-de-sac by catheterization of the bladder or vagina. At the same time he does not regard these indications sufficient to enlighten us as to the position of the cul-de-sac in the pelvis, that is, as to its accessibility by perineal incision.

Prolonged dissection in a difficult case is unjustifiable. The inguinal incision in such a case

The terminal attachment in imperforate rectum.

should be resorted to in preference to the perineal incision, on account of the superior precision in technic in the former, and the possibility of more exact avoidance of infection. This procedure likewise furnishes the most direct method of giving issue to the retained meconium. Exploration of the inguinal opening should be made during operation by the sound in order to determine the position and attachments of the rectum relative to the possibility of future perineal operation. Where the rectum can be brought down to such position as may permit its attachment to the perineal tissues an artificial iliac anus may be established temporarily.

Another method of operating may be followed by exploration of the position of the rectum, carried out by an incision in the neighborhood of the sacro-iliac articulation. The rectum may then be freed and its attachment to the incised perineum established. If it is found impracticable to force the rectum sufficiently downward an artificial iliac opening may be made instead of the perineal incision, the original exploratory opening being closed. This procedure, however, constitutes extreme surgical intervention and is scarcely justifiable under the average conditions in such cases. The iliac operation recommends itself in cases in which the symptoms of obstruction are grave or in which the treatment has been delayed. The infant two or three days old, with repeated vomiting, feebleness and rigors, must be the subject of prompt action, unless the obstruction appears to be due simply to a slight membranous bridging over of the anus and the cul-de-sac can be readily detected bulging against the perineum. Otherwise the indication is to open the anus at the point of election, namely, in the iliac region.

Trélat has emphasized the increasing danger of the situation as the case progresses. While in certain favorable instances the perineal incision may be utilized in the first few hours of the infant's life, it becomes, on the other hand, less and less admissible as the general accidents of the condition become more threatening. In such cases Forgue, therefore, considers it necessary to select the operation which will relieve the cause of obstruction most promptly rather than that which will restore the anatomical conditions. It is usually difficult to determine the degree of recession of the rectum and the extent of atresia. The reason for this is that when the rectum is suspended at the superior strait, the bladder and the vagina, being without support posteriorily, are apt to be displaced toward the concavity of the sacrum. The sacral excavation is, therefore, filled by these organs. As a result, exploration of the vagina or urethra by the sound is apt to be misleading, in that it does not reveal with certainty the presence or absence of the rectal ampulla, anterior to the plane of the sacrum.

Technic in Littré's Operation.

The abdominal wall is incised parallel to the groin at a distance of ¾ of an inch above Poupart's ligament on the left side. The incision must be made carefully owing to the abdominal distention, otherwise the gut may be punctured prematurely. The gut is first inspected as to its mesenteric attachment in order to determine its identity; then it is to be drawn up into the incision and stitched to the edge of the wound. The gut is afterward incised. Careful exploration by means of the sound as to the attachments and position of the rectum should then be practised in order to determine the data for future operation. The dressing should be carefully applied and frequently changed, inasmuch as the meconium and intestinal secretions are discharged in great quantity. The wound should be frequently inspected in order to detect the presence of hemorrhage, which is sometimes apt to occur from the edge of the wound. Fatal hemorrhage of this character has been reported by Hirst.

Forgue recommends the following technic in perineal incision: The infant, warmly enveloped,

is placed in the dorsal decubitus. The proper light is directed toward the field of operation. The thighs are flexed and supported. A sound is introduced in the bladder or vagina, according to the sex of the infant, in order to fix the median line as a landmark governing the direction and depth of the incision. The latter extends from the region of the anus, if it exist, or from the scrotum or fourchette, if the anus be absent, to the coccyx. The exploration should be as far backward, hugging the anterior surface of the sacrum, as possible. The anal infundibulum should be approached guardedly, and the tissues

The point of incision in Littré's operation.

examined attentively in the course of the incision. The field of operation should be carefully sponged and the connective tissue and fascial layers of the pelvic floor separated with care. Proceeding thus in order to discover the ampulla, the operator is guided partly by the sound in the urethra or vagina and partly by the examination of the tissues anterior to the sacrum and coccyx. The deeper incision should be made by means of blunt-pointed scissors. Finally, there is noticed in the wound a brownish distended sac, circumscribed by the denuded tissues. This becomes resistant and rounded, bulging toward the surface upon abdominal pressure. This is the blind extremity of the intestine. Should the rectum escape detection, it may be necessary to insert the little finger into the infant's pelvis up to the second joint; by passing a tenaculum along the finger the end of the rectum may be seized and pulled down. If it be still impossible to discover the position of the rectum the scissors are used to deepen the incision in the median line directly in front of the coccyx. The latter is then detached and removed. This resection of the coccyx increases markedly the field of operation and facilitates the exposure of the intestine. The gut is drawn down and carefully sutured to the anal region before it is incised, in order to prevent the infiltration of the surrounding tissues by the intestinal discharges and to give the rectum a fixed point of attachment. Great care should be observed in detaining the intestine at its point of future fixation after it has been disengaged and before the sutures are fully secured. Four or more sutures are introduced, an equal number on either side, longitudinally to the incision, including the skin and the wall of the intestine; by making gentle traction upon the sutures thus introduced, without tying them, the rectum may be drawn into position. A longitudinal incision of the gut is made from eight to ten millimeters in extent. The mass of meconium is then expelled. The operation is completed by the addition of sutures at the anterior and posterior commissures of the artificially-formed anus. The wound is carefully irrigated after operation and at each succeeding dressing. The napkin should be frequently changed in order to obviate the danger of irritation from the urine soaking through the dressings. The orifice should be dilated with the point of the little finger when the operation is completed. Later the finger should be introduced occasionally, at the time of dressing, and the wound should be inspected frequently in order to forestall the possibility of hemorrhage, which is likely to occur from the edge of the incision.

It may be observed here that the anal sphincter is frequently well developed in spite of the malformation of the rectum. The cicatrization which follows operation gives attachment to the muscular fibers which are present, so that the control of the rectum speedily asserts itself.

It is advisable to administer an anesthetic during operation in all cases in which careful dissection is required.

It is apparent from the foregoing that the treatment of imperforation demands, in order to determine the best procedure to be followed, first, the strictest observation of the anatomical condition present; second, a study of the condition of the infant, relative both to the urgency with which it may be necessary to relieve the obstruction, and to the ability of the infant to withstand a second operation.

GENERAL MEDICAL TREATMENT OF SYPHILIS.

BY G. FRANK LYDSTON, M.D.,

OF CHICAGO;

PROFESSOR OF GENITO-URINARY SURGERY AND SYPHILOLOGY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF ILLINOIS; PROFESSOR OF SURGERY IN THE CHICAGO CLINICAL SCHOOL.

THE pivotal point in the therapy of syphilis is of necessity the specific medication of the disease. In few or no instances, however, can specific medication alone be relied upon for a satisfactory result. In many instances the importance of specific medication sinks into insignificance before the general therapeutic indications present in the particular case. Specialism has done great harm by limiting the range of remedies useful in syphilis, independently of their specific effect. The success or failure of treatment in by no means infrequent instances depends more upon the general intelligence and therapeutic skill of the practitioner than upon the assiduity with which he carries out specific therapy.

The general hygienic management of syphilis is of fundamental importance. In many instances mercury and iodides act badly, simply because the patient's eliminative areas are not functionating with their normal activity. Injurious results from the drug specifics occur under such circumstances, and are explained by that explanation which does not explain, "idiosyncrasy." Ptyalism and iodism may both be avoided in many cases by attention to the eliminative functions. The ingestion of large quantities of water, with the concomitant increased functional activity of the skin, kidneys and bowels, is very useful in syphilis. This point is too frequently neglected. In giving iodides it is best, as is generally known, to administer them simultaneously with considerable quantities of water. It is impossible, however, without resulting stomachic disturbance, to give a sufficient quantity of water in this way to perfect elimination by the kidneys in certain cases in which the renal function is inadequate. It is in just such cases that iodism from so-called idiosyncrasy is liable to occur.

The best method of giving the iodide under such circumstances is to mix the daily dose of the drug with a given quantity of pure water, say from two quarts to a gallon, and instruct the patient to drink the entire amount, a glassful at a time, at intervals during the twenty-four hours. I have succeeded in avoiding iodism in this way in patients in whom the smallest quantity of iodide given by the ordinary method produced iodism.

Hot baths are a very useful adjuvant to the treatment of syphilis. They increase tissue metamorphosis, favor elimination, and necessarily enhance the therapeutic action of the mercury and iodide, while limiting any possible injurious effects of the drugs. In many instances hot baths alone will prevent injurious effects from mercury and iodide. A very hot bath of short duration, taken daily and followed by a cold shower or cold tub, is perhaps the best method of administration for the average patient. The ideal method, however, where its application is practicable, is the Turkish or Russian bath. The patient should drink large quantities of hot water while in the bath. Much of the efficacy of the Hot Springs treatment of syphilis is dependent upon the free ingestion of hot water while the hot bath is being given.

Attention to the bowels is very important in the treatment of syphilis. Ptyalism not infrequently results as a consequence of constipation. Obviously, the simpler forms of laxatives are best. The saline aperients taken hot in the morning are excellent. In many instances the substitution of a more active salt of mercury is followed by beneficial results when a tendency to constipation exists. In cases in which the bowel becomes irritated and, instead of being constipated, the patient is afflicted with diarrhea, the substitution of the tannate of mercury for the other preparations, or, in extreme cases, the use of the inunction or hypodermatic method, in lieu of the internal administration of the drug, gives excellent results.

In many instances the therapeutic efficacy of our antisyphilitic remedies is inhibited by digestive disturbance. Here, again, experimentation with various forms of the salts of mercury is often necessary to determine which particular salt is best tolerated. When the gastric symptoms are stubborn, the substitution of the hypodermic or inunction method is imperative. Lavage is sometimes of service in relieving the digestive disturbance and increasing the patient's tolerance for drugs.

When iodides are given, and the stomach and bowels are irritable, considerable trouble is often experienced in carrying out the treatment. When the fault lies with the stomach, the combination of essence of pepsin, plain or phenolated, with the iodide is useful. Taka-diastase is indicated when the irritation is largely of the bowel and starch indigestion exists.

In many instances in which syphilitic lesions, particularly of the mucous membrane, are very resistant to treatment and the patient apparently does not tolerate murcury and iodide well, the substitution of chlorate of potassium for these remedies is followed by most beneficial results. It should be given in ten-grain doses four times daily, largely diluted with water. It may be urged that this remedy acts only by antidoting certain evil effects of the iodide and mercury, which untoward effects are mistaken for symptoms of the disease itself. I am of opinion, however, that the chlorate of potassium, while in no sense a specific for syphilis, has a marked and positive action of its own in syphilitic lesions, more especially of the mucous membrane. Whether its property of hyperoxygenating the blood is responsible for the benefit derived from the drug is open to question, and is of but little moment. The clinical fact, I believe, remains the same, *i. e.*, that the chlorate of potassium is one of our most valuable remedies in the systematic treatment of syphilis.

He would be a careless practitioner, indeed, who did not realize the value of and utilize remedies of a tonic nature in the treatment of syphilis. In many instances the administration of simple tonics, such as iron and bark, will bring about a successful result in cases which are absolutely resistant to specific treatment, and which indeed seem to grow worse under it. It must be remembered that not only is syphilis debilitating, but full physiologic doses of mercury and iodide produce a distinctly debilitating effect, often with profound anemia. This anemia results not only from the perversion of nutrition caused by faulty digestion and assimilation induced by the irritating property of the mercury and the iodide, but from the special action of these drugs on the hematopoietic function.

The combination of the preparations of iron with mercurials, such as the pill duo, originally suggested by Otis, often obviates the debilitating

effects of mercury. In long-standing cases of syphilis the syrup of the iodide of iron is the most eligible preparation of the drug. The wine of coca, as suggested by Dr. R. W. Taylor, or, preferably, in my experience, the fluid extract, has a by no means unimportant action in avoiding debility in syphilitics. The combination of arsenic with the mixed treatment is useful, not only in combating debility, because of its marked tonic properties, but, as is well known, in inhibiting the effects of the iodide upon the skin. Iodide acne is very much less marked and is often avoided when arsenic is exhibited in combination with the iodide.

The cardinal principle which I desire to emphasize in the therapy of syphilis is that the physician should remember that he has to deal with three factors; first, a specific disease to be controlled by specific medication; second, a distinct, individual personality in each patient; third, the results of antispecific medication.

There is too great a tendency to treat syphilis and absolutely ignore the individual afflicted by it.

A CONSERVATIVE ELEMENT IN ACUTE MASTOID SURGERY.[1]

BY EDWIN W. PYLE, M.D.,

OF JERSEY CITY;

MEMBER OF THE NEW YORK ACADEMY OF MEDICINE; MEMBER OF THE NEW YORK OTOLOGICAL SOCIETY, ASSISTANT AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

Two years ago a country youth of healthy parentage and wholesome surroundings, while convalescing from scarlatina, suffered from an acute tympanic inflammation, followed by a purulent discharge which lasted two weeks, then abated with accession of pain and fever. The meatus was excoriated, fundus symptoms were pathognomonic, tenderness over the antrum was significant, with tumefaction extending from mastoid tip to temporal ridge. Operative suggestions did not meet with approval, but a compromise was effected in the hot bichloride douche and the patient kept under observation. Three days later all symptoms had become exaggerated, and, in addition, the integument involving the temple was red, tense, and imparted a sense of fluctuation. An immediate operation was advised and, upon this being refused, further responsibility was declined by the physician. The subsequent history was a continuation of douching, followed by gentle massage backward and downward, to dislodge pus from beneath the fascia into the external canal. Under the contracting influence of the former and the pressure of the latter, with general sustaining measures, pain, fever, and swelling subsided with recovery more perfect than could have been wrought by surgery.

The present condition is a slight tinnitus, watch-hearing distance 20 inches, and an area of cicatricial tissue in the posterior-superior quadrant. The operative indications were too pronounced to teach us conservatism under similar considerations; but the case illustrates that we do not always know what "might have been" under other circumstances, and that there are many similar experiences wherein Nature is the great physician.

Our profession has always had a monopoly in uncertain knowledge.

> "Whatever seed we may be sowing,
> The task that tries us most is—knowing."

The intricacies of the human mechanism and the spirit of life which pervades it are imperfectly understood. We are groping amid hundreds of reciprocal relations, numberless reactions, unlabeled conditions of various interpretations. When many of the grosser problems relative to function and to disease have been solved there remains the personal equation—the individualism which will always be an insuperable barrier to precise medical and surgical treatment. Our ignorance of the definite causes of pain, of that peculiar hyperesthesia which distinguishes nationalities, of the unforeseen manifestation of disease and recuperation, too often passes for real knowledge.

The illumination of the mysterious darkness that for centuries shrouded wound-infection has resulted in surgical transition with the promise of a still more brilliant day. A distinguished English physician observes that "in this very security, linked with our desires to meet the exigencies of the present, we unconsciously favor the tide of unrest which looms up with an ominous future." Though the average life be lengthened, disease and complaint are no less in evidence. People are no longer inclined to rest and to work out their health problems in natural processes, but run impatiently to surgery to have the same accomplished for them, knowing nothing of shock, nothing of failure, only its successes.

On the other hand, the specialist is apt to cultivate a morbid readiness to detect disease, to place the standard of health too high for practical purposes, forgetting that a good degree of being is compatible with innumerable departures from the normal standard. Health is relative; it is not a direct dial, pointing to zenith, but an arc of considerable latitude.

The pendulum swing between medicine and surgery tends to extremes. The excursion from the former to the latter in appendicitis has met with reaction in favor of time, but not until the penalty was paid in operating too early, thereby confounding the diagnosis with ailments of gastro-intestinal character. In gynecology pelvic surgery has become a too-absolute specialty, dissociated with the relative importance of the great sympathetic nervous system and the general field of scientific medicine. Dr. Goodhart tells us: "Organs have suffered from the lust of the people for operations and from the insufficiently non-repellant attitude of surgery."

Whereas these remarks are general, recent articles, differing from the conservatism of text-

[1] Read before the Otological Section of the New York Academy of Medicine, Oct. 9, 1901.

books, indicate that we are becoming more extravagant in our assertions, and are gradually approaching the surgical maelstrom. One writer makes the statement that mastoid implications are present in all severe cases of influenza, and that meningitis, sinus thrombosis, and other intracranial complications are becoming more frequent and alarming with each epidemic. Some deplore one or all of the abortive measures while observing the patient. Some would subject the mastoid to the same exploratory procedure as in abdominal surgery; and one is spreading the doctrine that mastoiditis is generally due to uricacidemia, and recommends operation when pain is elicited by pressure over the antrum, without waiting for the fundus symptoms. We have no desire to criticize the respective authors, or the specific conditions under which these suggestions originated. We question only the feasibility of general application and of inculcating radical sentiments to influence those of lesser attainments in aural surgery.

Were all equally skilled in technic and were congestion and granulation essentially operative, the blunt of exploration in doubtful mastoid necessities might be more cheerfully recommended; but under the existing conditions there is not an otologist who would not trust to antiphlogistic remedies until indications were pronounced, rather than submit himself to inexperienced hands, notwithstanding acute cases require less skill for successful performance. It is no trivial observation that physicians have a profound respect for their own end of the lash, and that inexperience is neither modest nor cautious. However commonplace operations may appear to the surgeon, to the laity they present serious phases that demand deliberate and conscientious consideration. The ablation of an apophysis costs little effort, but to the patient it may mean many weeks' absence from occupation as well as the dangers from the lack of thoroughness on the part of the operator. When we note how rarely meningitis accompanies acute mastoiditis, and how seldom in general practice brain complications are traceable to aural diseases as compared with other causes, surgical intervention should be more circumspect than in the chronic forms.

Were all equal as diagnosticians there would be less danger arising from misinterpretation of symptoms. The poet was not far wrong respecting mastoids when he said of affairs in general, "Things are not what they seem." After years of painstaking observation, who is not convinced of his diagnostic errors? Schwartze echoes this sentiment in his maturer writings. We grant that large experience gives intuitive knowledge; but wisdom, which is knowledge in its application to the exigencies of human necessities, is more apparent after the operation. One is stampeded to surgical inclinations because the bacteriologist announces the presence of streptococci, apparently unmindful that these organisms may exist in quantity with harmless effect; another, because the discharge is disproportionate to the size of the tympanum, a condition which may clear up speedily, and which is not infallibly due to mastoid complication.

Abnormal temperature, especially in childhood, may be coincident, making differentiation impossible, until the *primæ viæ* have been relieved and time has been given for the development of other symptoms to denote local or general disorder. Pain is so relative as to make its significance most difficult to gauge in the young and the hypersensitive. A persistence of this symptom—individualism rather than disease—has led to total ablations when there was no mastoid pathological evidence of the necessity. Tenderness over the antrum is equally misleading, yields frequently to the element of time, and is rarely in itself an operative indication.

The *tout ensemble* of the case should be considered—the primary or secondary nature of the attack. If primary, with resisting muco-periosteum and normal phagocytosis, amid conducive surroundings, the less skilful operator may well delay in reasonable doubt. If there be persistent narrowing of the deeper meatus, with concomitant symptoms of pus in the mastoid cells, or if the attack be engrafted upon a residual condition in an individual of vitiated blood, poor nourishment and ill environment, the early operation emphatically takes precedence. But when such complex symptoms are to be weighed in the balance, which can be trusted the more, the diagnostic ability of limited experience, or the granulation bulwark with which Nature invariably guards herself against pathogenic invasion?

To counsel delay with the use of antiphlogistic measures in acute mastoid inflammation is wiser than to encourage hasty operative procedures under blundering conceptions. The truth of this is most apparent to those who see the result of inefficient surgery, and emphasizes the necessity for careful instruction in such measures as all can apply with equal celerity and exactness. In no other ailment is it more imperative to know the significance of early rest and medication to reduce arterial tension, the importance of paracentesis to unload obstructed capillaries, the value of the ice-coil to retard bacterial activity, the wisdom of thermal douching to prevent mural implantation, to relieve congestion, edema, and pain. In no other ailment is it more imperative to mitigate suffering for a reasonable period of twenty-four hours. Even in recourse to analgesics, the periosteal character of the pain and the fact that temporary relief is sometimes the beginning of convalescence should be borne in mind. While observing the patient, every local, general, and detergent effort should be made to abort operative necessities. The intelligent application of such is not so confusing as poor surgery, nor should an occasional failure establish a general abolition.

The element of self-limitation has revolutionized therapeutical methods. While schools have contended over treatment, many diseases remain

uninfluenced except in response to the rule of Nature. Fehleisen discovered the streptococci which explain the phenomena of erysipelas; but why this process is propagated only to a certain period, when the organisms disappear, is still a mystery.

The ear is a minor part of God's handiwork, but governed by the same blood and sharing in the same law of limitation. Its anatomical adaptability is more complex than that of any other organ. To receive, to transmit and to analyze, instantly, the vibrations from whatsoever source, from all the varied noises and harmonies that can be produced in one's immediate vicinity, is marvelous beyond explanation. But the process of reparation is not dissimilar, nor is the manifestation of protective wisdom the less, because of this exalted function.

A careful search into aural histories and a close scrutiny of membranæ tympani must convince every observer that the natural tendency of acute otitis media is to recovery, even under questionable treatment. Bezold states that nine per cent. of acute middle-ear suppurations involve the mastoid to such an extent as to make spontaneous recovery improbable. These statistics may apply to crowded cities, but they are not true respecting small towns and environments. There is no more significant fact than that the general practitioner is greatly in evidence during epidemic influenzas, and that his acute aural cases involving the mastoid rarely require operative necessities.

In defense of this assertion we give the following approximate statistics, gathered from the experience of twenty-five physicians variously located. All are representative practitioners of more than ordinary acquirements, and several are surgeons of excellent repute. These physicians aggregate in practise five hundred years, and have had eighty cases of acute mastoiditis following middle-ear inflammation come to operation; or, in other words, each of these physicians has had an operative case once in about six years.

These numbers will seem incredible to those accustomed to the frequency of acute mastoiditis in many of our institutions especially fitted to treat this affection; but they are verified by noteworthy experiences. Dr. G. K. Dickinson of Jersey City, distinguished for diagnostic, medical, and surgical ability, reports that in twenty-four years he has not seen more than six cases. Dr. John Seward of Orange, a most conscientious observer in the interest of his *clientèle,* has had three cases in thirty-two years. Dr. Brodnax, an encyclopedia of medical knowledge pertaining to his country in Louisiana, has never known such a complication. In one instance only was there an adverse report. Dr. Guthrie of Wilkesbarre believes that operative cases of acute mastoiditis following grippe epidemics are relatively numerous and particularizes the years 1889-90.

The complete report, however, conforms to my own experience. From 1873 to 1897, devoted exclusively to general practice, during which time I had the medical supervision of several hundred families, two cases of acute mastoiditis came to operation and four of subperiosteal pus accumulations made excellent recoveries under the Wild's incision. From 1897 to date almost exclusive study has been given to aural diseases, yet during this period there has not been the suggestion of an operative case in my medical acquaintanceship, which confirms that but little was overlooked in earlier years, and only eight have been referred out of all the experiences of fellow practitioners.

The explanation must be sought in two conditions. First, it emphasizes that peculiar reciprocal relation between demand and supply. In the abundant opportunity of this world honest effort can invariably find the object of its search. We have only to prepare ourselves for definite work, and then await the tide of human affairs. It verily seems that were one to devote his special energies to the repair of dislocated necks, under the patronage of an endowed institution, he would soon be confronted with a thriving business. A second explanation is in the individuals and their surroundings, in the relief afforded by treatment, and in the protective influence of Nature. The operation of natural laws varies with different orders of beings through the influence of habit, heredity, and environment. Though Nature does not directly provide man with a home or a dress suit, it must be admitted that in most acute cases and in many chronic conditions she guards well her own interest, even when both physician and surgeon are *hors de combat.*

In our institutions the facts respecting successive operations point to error on the part of conservatism; but to advocate exploratory operations or early operative procedures in acute mastoid inflammation, before the fundus symptoms are significant or before local and general antiphlogistic measures have had due prominence, proceeding from medical centers to go throughout the land to influence those who treat under circumstances differing materially from our own, is too radical to secure the greatest good to the greatest numbers.

Experience gained and conclusions formulated from clinical services in a large city like New York are but relative to a class of people more or less vitiated by dyscrasias and burdened by unwholesome surroundings. Knowledge derived from such sources should not be applied with too great fervor in those sections of country where blood, food, and climate are most conducive to recuperation, and where tissue-resistance is more potent to limit extension.

In the early operation, the experienced surgeon with clear conception and faultless technic *may* save life and function; but in the hands of the many the protective and the reparative processes of Nature will be abetted *more* and embarrassed *less* by rational antiphlogosis than by meddlesome surgery.

612 Bergen Avenue.

THE CLASS OF CASES OF SIMPLE CHRONIC GLAUCOMA IN WHICH OPERATION IS NOT ADVISABLE.[1]

BY CHARLES STEDMAN BULL, A.M., M.D.,
OF NEW YORK.

In the years which have elapsed since Von Graefe first suggested the operation of iridectomy for the relief of glaucoma, our views as to the value of this method of treatment in all forms of glaucoma have undergone material modification. Your Chairman has asked me to present to the Section on Ophthalmology a paper upon the subject of "those cases of glaucoma in which operation is not advisable," and, in accepting his invitation, I have decided to confine what I have to say to the subject of *simple chronic glaucoma.*

The complete divergence of opinion as to the relative value of various methods of treatment in simple chronic glaucoma is probably due to a lack of precision in interpreting the real meaning of the various symptoms as they are observed in different cases. In the actual state of our knowledge, it is difficult always to distinguish between the intermediate forms which present themselves to our notice. It is known to us all that some cases are called simple chronic glaucoma by one class of authors, while the same are classed as inflammatory or irritative chronic glaucoma by other authors of equal repute. May it not be wise to regard simple chronic glaucoma as a disease in many respects essentially different from glaucoma with exacerbations? We should also never forget that the symptoms which are supposed to characterize simple chronic glaucoma, viz., reduction of vision, narrowing of the visual field, and excavation of the optic disk, are not characteristic of the disease, for they are all met with in simple atrophy of the optic nerve.

I am inclined to think, partly from my own experience and partly from the expressed opinions of some of my colleagues on the subject, that the unfavorable view taken of operative procedures in simple chronic glaucoma is often due to our errors in diagnosis. We must learn to distinguish absolutely between simple chronic glaucoma and a diseased condition of the optic nerve with pre-existing physiological excavation, and the distinguishing sign is the increase of the intra-ocular tension. Without this *increase of tension* there is no *glaucoma.* Here is the great difficulty, for in simple chronic glaucoma the increase of the intra-ocular tension is often so slight as to be far from easy to recognize, and in these cases we may readily confound the disease with atrophy of the optic nerve. Moreover, in this form of glaucoma increased tension is not constantly present, and may be absent for hours and even days in succession. In fact, as we know, the disease presents no active symptoms and it is difficult to fix the date of onset. These periods of increased tension should be searched for with the finger-tips placed on the sclera itself and not on the closed lids. I make the examinations frequently at different hours of the same day or different days. I think we are justified in saying that in every case of simple chronic glaucoma there is a slow but progressive increase in the tension, not always to be recognized at first, but which becomes demonstrable after repeated examinations.

Some writers are of the opinion that this false or pseudoglaucoma simulates the real glaucoma in about half the number of cases of so-called simple glaucoma. If we confound the two diseases with each other, we may be guilty of a double error, for the false glaucoma should never be treated surgically, and, if the case be a true glaucoma, we may deprive the patient of its real surgical remedy. A possible explanation of the failure of both iridectomy and sclerotomy to bring about a cure in all cases in which the tension is not increased may be in the fact that they exert no effect in reducing normal tension, but only produce this effect in cases in which the tension is increased. In studying our cases of glaucoma, we may sometimes gain assistance from observing the existing conditions of the angle of the anterior chamber. The form of the filtration angle varies with that of the ciliary muscle. In emmetropic eyes the angle is wide and the peripheral origin of the iris is variable. In hypermetropic eyes, the peripheral origin of the iris is displaced inward toward the axis of the eye, and the angle of the chamber is narrowed and pointed. In myopic eyes, the origin of the iris is displaced outward away from the axis of the eye, and the angle of the chamber is rounded and wider. Hence the angle is more apt to be closed by the glaucomatous condition in hypermetropic eyes, and less so in myopic eyes.

A careful and frequently repeated study of the field of vision will often yield valuable information, helping us to a decision for or against operative interference. The defects in the field in glaucoma often represent peculiar types, and it should here not be forgotten that disease of the retinal vessels sometimes causes defects of the field of vision which show a certain analogy with glaucomatous defects. We do not always meet with the typical contraction on the nasal side, for there are frequent exceptions. It is also well to remember that the personal equation of the observer should always be considered in examinations of the visual field. To one observer a field may appear contracted and to another observer uncontracted. But if we find that the visual field is on successive days and at repeated examinations contracted on the nasal side or concentrically, we may be sure that the disease is progressing. If the field be examined with white objects under small visual angles, according to the plan recommended by Bjerrum and Meisling, or by squares of gray paper, as suggested by Holden, we can often demonstrate a much greater functional disturbance of the field of vision than by the ordinary perimetric examinations.

[1] Read before the Ophthalmic Section of the Academy of Medicine, Nov. 18, 1901.

I agree fully with De Schweinitz that the existence of scotomata in the field aids us in forming a prognosis in simple glaucoma. They are frequently the forerunners of subsequent peripheral defects in the visual field. I do not consider, in any doubtful case, that the field is thoroughly mapped out until each meridian has been examined from fixation point to periphery and under varying degrees of illumination, both for white and colors. The scotomata may be central or paracentral, but are topographically different from those met with in atrophy of the optic nerve. We know that the prognosis depends on the type of the disease and the stage of its development. Much also depends, in the chronic cases, upon the amount of degenerative change in the retina, measured by the defects in the visual field.

We may also gain some insight as to the result of an operation in a given case from the condition of the iris and its reaction to myotics, and in some cases this behavior of the iris furnishes a good prognostic guide for operative interference. The most important point in the management of chronic glaucoma is that our *diagnosis* should be *correct,* and we should be careful never to base our diagnosis upon the presence of one or even two symptoms, but we must look for them all, even if we are forced to reserve our diagnosis until the patient has been examined a number of times.

The study of the disk in chronic glaucoma is often misleading. Total excavation of the disk as far as its edge often exists without any increase of tension demonstrable by the finger. Schweigger is probably correct in saying that the term "physiological excavation" should only be employed when it involves more than one-third of the papilla and shows at the bottom the lamina cribrosa. The ophthalmoscopic picture of physiological excavation may be produced by glaucoma, and a large physiological excavation with discoloration of the disk often cannot be distinguished from a pressure excavation. Here the diagnosis is very difficult, for the ophthalmoscope cannot tell which process came first. The pre-existing physiological excavation, in consequence of a secondary atrophy of the optic nerve, may eventually coincide all round with the scleral margin of the disk, and give a picture of "typical glaucomatous excavation" without glaucoma. In the optic nerve atrophy, due to spinal disease, we have such a clear clinical picture that we are not likely to err in our diagnosis. In the rare primary atrophy of the optic nerve, however, we may easily err and confound it with chronic glaucoma. Hence these cases should be carefully followed for a length of time. The condition of the iris and pupil is not always diagnostic. A chronic glaucoma may go on to blindness without affecting the reaction of the iris to light. The pupil may be perfectly round and yet the iris be dilated and movable. The condition of the anterior chamber is not always diagnostic, for, though generally shallow in chronic glaucoma, it may regain its normal depth.

I have seen the diagnosis of glaucoma made from the presence of arterial pulsation. This I consider a mistake. The arterial pulsation is probably often present when not visible. When present in connection with the other symptoms, I regard it as a grave symptom, indicating the possible occurrence of retinal hemorrhage after iridectomy.

The question of tension is probably the most difficult one to settle in chronic glaucoma. Schweigger says that there are *physiologically hard* and *physiologically soft* eyes, and that he does not recognize any normal limit for the tactile hardness of eyes, because the resistance to the finger depends not only on the intra-ocular pressure, but also on the resisting power of the sclerotic, which is very different in different individuals and at different points. In simple chronic glaucoma the increase of tension is very apt to appear in a sudden attack, which at first lasts a brief period and then disappears; but as the disease becomes more chronic, the increase of tension occurs more frequently and lasts longer, until in the pronounced cases it is a permanent feature.

In What Class of Cases of Simple Chronic Glaucoma is Operative Interference Not Advisable?—This question may perhaps be best answered by a process of exclusion.

My experience with sclerotomy has not been satisfactory. It has not in my experience given lasting results, though it may be regarded in a measure as preparatory to iridectomy in cases with very high tension, or, in very nervous, uncontrollable patients, as a palliative. What little I have to say under the head of operative interference will therefore be confined to iridectomy.

Simple chronic glaucoma should always be operated on early in the disease, before much contraction of the field has occurred. The operative effect of iridectomy is more certain and undeniable the earlier it is done. The slightest narrowing of the field, whether for form or color, demands operation once our diagnosis is made. The curative action of iridectomy stands in direct proportion to the increase of tension. Early iridectomy, while the iris is still mobile, the field but little contracted, and the cupping of the disk slight, commonly arrests the disease, at least for a prolonged period, and preserves what sight remains. *Done early,* it offers the best prospect for the arrest of the process, and its effects are either permanent or very prolonged. If the tension is lowered after iridectomy, a favorable result is to be expected. If the tension remains high after operation, we must look for an unfavorable result. If, under the use of myotics, the vision improves and the field widens, it is almost certain that an iridectomy will give a good result. If, in spite of myotics, the visual acuity remains stationary and the field does not improve, the effect of the operation will be less favorable.

In advanced chronic glaucoma with great contraction of the visual field, marked impairment

of the vision, undoubted increase of tension and deep cupping of the disk, the prognosis for operation is more than doubtful; it is distinctly unfavorable, and iridectomy should not be done. In those cases in which the contraction of the visual field has approached close to the fixation point, even though the central vision is still good, iridectomy is positively contra-indicated; for the contraction of the field is not arrested, is often made immediately worse, and may be followed by total loss of central vision.

What Can Be Done for Those Cases in Which Operation Is Not Advisable?—Something there is in the way of treatment which may retard the progress of the disease, even though it does not effect a cure. If we can bring about contraction of the iris and lower the intra-ocular tension, even though the field may not be widened nor the vision improved, we at least render the progress of the disease more slow, and for a time maintain the vision at the existing standard. For these results we rely mainly though not entirely on myotics. These are of no use unless they contract the iris and lower the tension. They can never bring about a radical cure. Hence they are of little use in old, advanced cases of glaucoma, in which the iris is atrophied. Of the two myotics, eserine and pilocarpine, eserine is the more powerful agent, but it is the more irritating and tends to develop ciliary congestion. Its use is best combined with cocaine, which contracts the caliber of the ciliary blood-vessels and diminishes the sensibility of the ciliary nerves. It should be remembered that the congestion of the ciliary processes induced by eserine often entirely defeats its desired effect, and, moreover, its prolonged use tends to cause a follicular conjunctivitis in many eyes. The combined effect of eserine and cocaine is myosis with reduction of tension, due to the paralyzing influence of cocaine on both nerves and vessels, which prevents the swelling and congestion of the ciliary processes induced by the eserine. Eserine should be used in the minimum amount and with the minimum frequency which suffice to contract the iris and keep it contracted. The form in which we use the drug is a matter of some practical importance.

The salicylate and hydrobromate compounds are more permanent and less changeable in solution than is either the sulphate or hydrochlorate. When the effect of the eserine in contracting the iris and lowering the tension has been produced, it is well to continue these effects by the use of pilocarpine. Another point to be remembered is that eserine sometimes fails to lower the tension, while pilocarpine succeeds. Wicherkiewicz thinks that this is probably due to the following existing conditions: In a highly developed condition of Müller's fibers of the ciliary muscle, eserine causes marked swelling of the ciliary processes. If in such a case there are a small eyeball, a narrow circumlental space, and a large lens, eserine may bring about complete closure of the space between the vitreous chamber and the posterior chamber, which causes marked obstruction to the exit of fluid from the vitreous into the anterior chamber. This condition does not occur when pilocarpine is used. Hence after the eserine has drawn away the iris from the angle of the anterior chamber and has lowered the tension, it is wise to change to pilocarpine, and allow the congestion of the ciliary processes to subside.

The primary effect of the eserine may be assisted by a hypodermic injection of morphine, five to eight minims of Magendie's solution, which lowers the blood-pressure, lessens secretion and promotes contraction of the iris. I am in the habit of beginning with a solution of eserine salicylate, gr. $^1/_{10}$ to $^1/_4$, and cocaine hydrochlorate, gr. ij, and after two or three days' use of this solution, instilled two or three times a day, I change to a solution of pilocarpine hydrochlorate, gr. ij, and cocaine, gr. i, used with the same frequency. If I find after a time that the iris tends to dilate or the tension to rise, I revert to the use of the eserine solution for a few days.

Some of the preparations of pilocarpine contain an impurity in the form of *jaborine*, an isomer of pilocarpine, which has a mydriatic action on the iris. This is not a definite single compound, but a mixture of pilocarpine with closely-allied alkaloids, like isopilocarpine. Attention has been called to this point recently by Lilienfeld (Centralblatt für prakt. Augenheilkunde, May and June, 1901), who suggests that the pilocarpine preparations should be first subjected to careful physiological tests, before being placed on the market. This would minimize this danger.

I have occasionally found that gentle massage of the eyeball has been followed by improvement in the vision and deepening of the anterior chamber, and I therefore advise it twice a day as a part of the routine treatment. Before instituting any local treatment, these eyes must be carefully examined for any refractive error, and, when found, this must be fully corrected by glasses. The habits of life of the patient should be regulated as far as possible, and all excesses of every kind should be avoided. The eyes should be employed in close work as little as possible, and with frequent periods of rest. If there be a tendency to constipation, this should be regulated, for it is well known that aperients sometimes produce a very decided effect on the tension and congestion of the eye. Avoidance of everything tending to the production of anxiety or mental disturbance is an additional precaution to be distinctly impressed upon the patient.

Regular hours and habits, and sound, refreshing sleep are all important in the management of this rather hopeless class of cases. Any existing gouty or rheumatic tendency should be treated by appropriate remedies, preferably the sodium salicylate, alternating with alteratives and strychnine.

A RESUME OF THE SUBJECT OF ACTINOMYCOSIS, WITH REPORT OF A CASE OF ACTINOMYCOSIS ABDOMINALIS.[1]

BY A. VAN DER VEER, M.D.,
AND
ARTHUR W. ELTING, M.D.,
OF ALBANY, NEW YORK.

THE polymorphous fungus causing this lesion belongs to the general group of *Oöspora* and was first recognized by Von Langenbeck in 1845. In 1857 Lebert described a case of thoracic actinomycosis observed by Louis in 1848, and published illustrations of the actinomyces in his Atlas. He believed, however, that these fungi were the detritus of cysticerci.

From 1868 to 1875 Rivolti and Perroncito demonstrated that the so-called sarcomata of the jaws of cattle were due to actinomyces; Bollinger, at the same time, recognized the characteristic fungus in "lump jaw" in cattle, and referred it to the botanist Harz, who classified and gave to it the name of *Actinomycosis*.

Actinomycosis in human pathology dates from the works of Israel in 1878, when this author and Ponfick recognized the identity of bovine and human actinomyces, even before the transmissibility of the disease had been proven by inoculation experiments. These latter were not successful until 1880, when Johne produced the disease in a cow inoculated with some of the actinomycotic granules obtained from an animal of the same species. In 1883 Israel successfully inoculated the human actinomyces into a rabbit.

During the decade from 1880 to 1890 there were published two important articles, *i. e.*, the classical monograph of Israel in 1885, with a report of 37 cases of human actinomycosis, comparatively little having been added since; the second article was published by Böstrom, in which he paid special attention to human actinomycosis, and the transmissibility of the disease through vegetable life. During the past decade much interest has been aroused in France, and among the best of the numerous publications is the exhaustive monograph of Poncet and Berard. To-day the American literature on the subject is very extensive, the disease no longer being regarded as of infrequent occurrence.

A great variety of names has been proposed for the fungus, and it has often been confused with Madura foot. The true distinction, however, between Madura foot and the group of pseudo-actinomycoses was clearly established by Blanchard in 1895.

In infected tissue, contents of abscess cavities, or discharge from fistulous passages, the actinomyces are usually present in the form of small, yellowish, more or less opaque granules, in size from .15 to .75 mm., although larger granules often occur. They are usually gravish-white, transparent, easily broken up, and of the consistence of soft jelly. As they get older, the granules grow more opaque and yellow, and, finally becoming impregnated with calcium salts, give rise to structureless concretions.

The actinomyces stain readily with ordinary basic aniline dyes, are not decolorized by Gram's method, are facultative anaerobes, and grow upon most of the common bacteria culture media. The best temperature for their growth is from 33° to 37° C. Even under the best of conditions their development in culture is slow, requiring from five to fifteen days. Very often actinomyces are commingled with other micro-organisms. These latter usually grow more vigorously, and tend to obscure the former. The most common of these micro-organisms are staphylococci, streptococci, the colon bacillus and leptothrix buccalis.

Actinomyces possess a surprising ability to develop upon cereals and vegetable media in general. At 45° C. the growth of the fungus is arrested, and it is rapidly destroyed at 60° C. The spores are more resistant to injurious agencies than is the mycelium, although less so than the spores of bacteria. Greater resistance to noxious agencies is possessed by the spores grown upon cereals, experiments by Berard and Nicolas showing that some spore had lived as long as four years upon certain cereals even under unfavorable conditions.

There are a few cases in record in which it seemed probable that man had contracted the disease from animals, but it would appear that prolonged, intimate and close contact is necessary, which seems to indicate that the virulence and infectiousness of the actinomyces are diminished in animal organisms.

The consensus of opinion is that the great carriers of actinomycotic contagion are the different forms of cereals, especially barley, and that through their agency both man and the domestic animals become infected. Pieces of cereal grains have been found in the focus of infection. Vegetables, especially those grown above ground, may also convey the organism to man and to animals.

Men are much more frequently infected than women, probably as a result of their being more exposed to infection. Of 357 cases of human actinomycosis collected by Hutyra, one-third occurred in the third decade of recognition of the disease.

Four chief avenues of infection have been distinguished, viz: (1) through the mouth and pharynx; (2) through the respiratory tract; (3) through the gastro-intestinal tract; (4) through skin-wounds, etc. There is also a group of cases in which no definite portal of entry is discoverable.

Microscopically, a focus of actinomycotic infection is characterized by a central zone that contains the fungus, either free or attached to the foreign body by means of which it gained access to the part. This zone usually contains more or less cellular detritus and the products of degeneration. The blood-vessels in the immediate vicinity of the focus are rarely obliterated.

[1] Abstract of a paper read at the semi-annual meeting of the Medical Society of the State of New York, October 16, 1901.

All the actinomycotic lesions can be divided into two great classes: (1) The neoplastic type, which is usually found in horses and cattle; (2) the inflammatory type, usually found in man and hogs.

The neoplastic type is the form in which spontaneous recovery not infrequently occurs. In the inflammatory type the process of destruction exceeds that of defense both in rapidity and in intensity, and tends to the production of sinuses but not of large abscess cavities. These latter are usually the result of secondary infections.

The muscles and bones afford a very unfavorable medium for development or extension of actinomycotic foci. The tendency to the formation of fistulous passages is very characteristic, the discharge presenting marked differences. In some instances it is serous, in others sero-purulent and in still others distinctly purulent. Secondary infection exists in practically all fistulous cases. Another characteristic feature of actinomycotic lesions is the tendency to extend by continuity rather than by metastasis.

Poncet and Berard propose a division of actinomycotic infections into the following groups: (1) Cervico-facial; (2) thoracic; (3) abdominal, and (4) cutaneous; foci in bone, the spinal column, the genito-urinary organs, the brain, special organs of sense, etc., being regarded as complications.

Statistics prove that about 55 per cent. of the cases are of the cervico-facial type; 20 per cent. thoracic and pulmonary; about 20 per cent. abdominal and about 5 per cent. of a variety of types.

There has never been a definitely authenticated case of primary abdominal actinomycosis reported which did not originate from the gastro-intestinal tract, adhesions and abscesses being the characteristic features, the abscesses always resulting from a secondary infection. The actinomyces gain access to the stomach either with animal or with vegetable food, most commonly the latter. Neither the gastric juice nor the bile appears to have any very decidedly harmful effect upon the fungus. The different portions of the alimentary tract then seem to be affected in direct proportion to the length of time that the intestinal contents remain in the different parts.

Intestinal actinomycosis appears first as a small nodule in the submucosa. This undergoes degeneration at its center, and presently gives rise to a small ulcer with undermined edges which may extend either by progression or by confluence of several small ulcers, which, in certain instances, heal and leave irregular pigmented scars. As the process extends there is a distinct tendency for the involved portion of the intestine to become adherent to other portions of the intestine, the abdominal viscera or the abdominal wall, preventing, in most instances, a perforation into the general peritoneal cavity. When the process originates from the colon, *i.e.*, a portion of intestine not provided with a mesentery, retroperitoneal abscess is not an uncommon complication.

In some instances the intestine adherent to the abdominal wall has perforated externally, forming a fecal fistula. Perforation into the bladder is of rare occurrence, although cases have been reported by Böstrom, Hesse, Billroth and others. The prostate has, in a few instances, been involved by extension of the disease from the rectum. In women the pelvic viscera have sometimes been extensively involved by extension of the process from the primary intestinal focus. In all the literature Grill was unable to find a single authentic cases in which abdominal actinomycosis had extended through the lymph-channels. Metastasis, in the great majority of cases, takes place through the veins rather than through the arteries. Among the secondary lesions of abdominal actinomycosis those of the liver are the most frequent, involvement occurring either by continuity, contiguity or metastasis. In 20 of the 30 cases of hepatic actinomycosis collected by Aribaud the primary focus was intestinal.

In from 50 to 60 per cent. of abdominal actinomycosis the primary focus is in the cecum, appendix, or contiguous portions of the ileum and colon *i.e.*, in the right iliac fossa; in from 10 to 15 per cent. of the cases in the rectum. In comparatively few cases has the primary focus occurred in the small intestine. There thus remain a certain number of cases in which the primary focus is undetermined, even though careful postmortem examinations have been made.

Grill has distinguished three typical periods in the course of abdominal actinomycosis: (1) The initial period; (2) the period of tumor formation; (3) the period of fistula. To these three periods Hinglais has added a fourth—a period of repair. Although in certain cases this or that period may predominate or be entirely absent, nevertheless the periods mentioned are usually characteristic of the disease when localized in the abdomen. Pain, while usually present, is rarely severe, being rather a sensation of tension and discomfort.

In rectal actinomycosis the fistulæ usually open about the anus and occasionally in the loin or above the pubis. Spontaneous recovery is possible, even though there be extensive infiltration of the abdominal wall with numerous fistulæ.

The duration of the disease is quite variable—from a few weeks to several years.

The prognosis in abdominal actinomycosis, even though the process be extensive, is not necessarily hopeless, for there are on record a large number of cases in which recovery resulted. In general one can say that those cases offer the best prognosis which are most amenable to surgical treatment, *i.e.*, the abdominal form rather than the thoracic. The oldest cases are most unfavorable because of the possibilities offered for extension or metastasis. In 77 cases of abdominal actinomycosis treated surgically Grill found 22 recoveries, 10 improvements and 45 deaths.

It is practically impossible to recognize abdominal actinomycosis in its earliest stage, al-

though examination of fecal matter has, in a few instances, led to a comparatively early diagnosis. In the later stages, when tumefaction is extensive, with foci of suppuration and numerous fistulæ, and the discharge contains characteristic granules, diagnosis is comparatively easy. Sarcoma, carcinoma and tuberculosis of the cecal region must also be considered in differential diagnosis.

Greater care in the selection and preparation of cereals and vegetables would certainly diminish the number of infections by this avenue. Since thorough cooking destroys the spores of actinomyces in flesh, prevention of the infection from this source would appear to be comparatively easy.

Therapeutically a so-called specific for actinomycosis has never been discovered, although iodide of potassium possesses certain qualities which bring about favorable results. In general, iodide of potassium appears to act more satisfactorily and effectually the earlier in the course of the disease it is administered and in large and gradually increasing doses. Experiments have shown that it has little or no effect upon the growth of the actinomyces on artificial media.

Billroth, Kahler and others have tried the effect of tuberculin, improvement seeming to have followed its employment in a few instances. An interesting fact brought out by Kahler, Illich and Wolff, and confirmed by Arloing, is that men and animals infected with actinomycosis react to Koch's tuberculin the same as do cases of tuberculosis. Ziegler has reported a favorable result following the injection of protein obtained from cultures of the staphylococcus pyogenes aureus. Gautier has seen favorable results follow the use of electrolysis, and Braum recommends the use of Fowler's solution. In general, however, combined medical and surgical treatment would appear to have produced the best results, especially in the forms of actinomycosis more superficially placed.

It is frequently difficult to determine the extent of the process and consequently the extent of surgical intervention required. Careful exploration of the fistulæ and foci should be practised, so far as possible, with the removal of as much diseased tissue as consistent. If apparent recovery occur, the case should nevertheless be watched for several years because of the great possibility of recurrence.

Case I.—A. S., Castleton, N. Y., aged forty-five years, native of United States; carpenter by occupation; married. Admitted to Albany Hospital, February 22, 1901. Provisional diagnosis, sarcoma of cecum or mesentery; corrected diagnosis, actinomycosis abdominalis. Treatment, operative and medical. Family history good. Patient had usual diseases of childhood; typhoid fever at the age of fifteen; was very ill, but made a good recovery. Denies venereal disease of any kind. Patient has partaken sparingly of stimulants; smokes and chews tobacco somewhat excessively; has associated much with animals; never worked in grain. General health always good; no serious injuries.

Present illness began November 27, 1900. While at work had pain in stomach; however, finished day's work and then tried various remedies without relief. Had sharp cramps in lower portion of abdomen; very severe for three or five minutes, recurring at first every half hour or so. Did not obtain relief for a week, although under the care of a physician. Pain gradually diminished, but did not disappear for eight weeks from onset. No chills, fever or vomiting, but slightly nauseated. Pain not localized nor radiating, but seemed to patient to be in abdomen. No jaundice; no distention of abdomen that patient ever noticed. Bowels and kidneys normal in functions.

January 1, 1901, patient was able to be up and around and improved quite rapidly. Middle of January he superintended an ice gang. February 1st, as well as usual, and had regained normal weight. February 20th, still feeling as well as ever, but noticed a small tumor in region of umbilicus, for which he came to the Albany Hospital February 22d, under my care.

Physical Diagnosis.—Distinct tumor, size of a fist, in right iliac region; smaller tumor, inflammatory in character, evidently containing pus, at umbilicus; smaller masses to be felt through and in abdominal wall, giving an impression of sarcoma of the mesentery. Heart, lungs, spleen and stomach normal. Liver dulness extended about one finger-breadth below costal margin. Skin over tumor red, with yellow spot in center. Urine amber, 1030, acid, no albumin nor sugar, sediment slight, and a very large number of calcium oxalate crystals present. Blood examination revealed leucocytes, 18,500; red cells, 4,710,000.

Operation February 28, 1901: Abdominal incision 6 cm. long in median line. Peritoneum found adherent to coils of small intestines in various places, with a flattened tumor, size of half a hand, springing from right iliac crest. While supposed to be a case of multiple sarcoma of the mesentery, it differed from any case I had ever seen. There was a distinct hardening of this portion of the peritoneum extending to the umbilicus, along the course of the urachus and round ligament of the liver, with an abscess presenting just under the skin. The latter was not opened for fear of infecting the peritoneum. Incision in peritoneum closed wtih fine silk, continuous sutures; wound closed with interrupted silkwormgut sutures and iodoform gauze introduced in lower end of incision, then standard dressing. The gauze was removed on the fourth day, and drainage encouraged thereafter, the abscess of the umbilicus having opened and discharged a creamy, flake-like substance. Specimens of discharge and tumor were saved, but lost later, and did not reach the Bender Laboratory for examination.

The patient was put upon syrup of hydriodic acid, strychnine and elixir of calisaya, with as good nourishment as possible.

Not feeling at all certain of my diagnosis and fearing the possibility of actinomycosis, about April 1st I asked Dr. Elting to look the patient over carefully and make a thorough examination

Fig. 1. Abdominal actinomycosis. August 3, 1901.

of the discharge. This was done and the case found to be one of typical actinomycosis. Coverslips stained by Gram's method showed the characteristic fungi. Cultures from several of the ab-

Fig. 2. The same.

scesses showed so vigorous a growth of the bacillus coli communis that the growth of the actinomyces was obscured. The patient was now given iodide of potassium in increasing doses, *i. e.*, a saturated solution, commencing with three drops in a wineglassful of water before each meal, increasing three drops each day until sixty drops were reached and this dose continued.

May 1, 1901: Condition has improved some-

Fig. 3. The same. October 12, 1901.

what, although it was necessary on two occasions to open abscesses in the abdominal wall. Less numerous actinomycotic granules in discharge than before the administration of iodide of potassium was begun. Large tumor still in right

Fig. 4. The same.

lower quadrant of abdomen, extensive induration and infiltration of abdominal wall, and four fistulous openings.

June 15th: Patient's general condition not quite so satisfactory as at previous note. Three

discharging sinuses in abdominal wall, the discharge seropurulent, and containing a moderate amount of actinomycotic granules. Appetite good—no gastrointestinal symptoms. At patient's request he was discharged from the hospital and advised to continue the large doses of iodide of potassium.

June 29th: Patient re-admitted to hospital for further observation. General condition somewhat improved, but there are more discharging sinuses than at last note. Condition at this time indicated by accompanying photographs. (Figs. 1 and 2.)

August 20th: Patient returns feeling much better than when seen about three weeks ago. Condition of abdomen distinctly improved. Some of the sinuses closed, and the discharge from the remaining ones decidedly less. Patient says two weeks ago a small pimple or blackhead developed on right side of the nose, near inner angle of eye. This was squeezed by his wife, who had attended to the abdominal wounds. Forty-eight hours later patient noticed some pain and swelling about nose, which gradually increased, and a tumor the size of a hen's egg developed, which almost entirely closed the right eye. Hot applications were employed and about a week from onset tumor broke and discharged considerable pus. There still remains a tumor the size of a large pigeon's egg, the skin near and around presenting a livid appearance. Discharge seropurulent and containing a few typical actinomycotic granules. Potassium still continued.

September 20th: Patient returns feeling much improved. Abscess of nose entirely healed. Abdominal condition much improved. There are still a few actinomycotic granules in discharge from sinuses in abdominal wall.

October 12th: Patient shows still further improvement. Has been doing light work for several weeks past. Color good and general appearance excellent. Four or five discharging sinuses in abdominal wall, containing a small amount of discharge, with an occasional actinomycotic granule, mostly in an early stage of development. Condition of patient's abdomen at this time indicated in Figs. 3 and 4.

If this case is studied carefully it is very striking to observe the characteristic conditions that have been described by many authors, *i.e.*, the tumors to be felt in the peritoneal cavity and in the abdominal walls, the peculiar reddish-blue appearance of the surface of the abdomen, the multiple abscesses containing yellowish pus and granules. All of these conditions are indicative of actinomycosis; also the patient's improvement for a time after operative intervention and still further improvement when getting under the full effect of the iodide of potassium, the infection of the nose, and the rapid recovery, all aid in confirming the previous diagnosis.

The photographs illustrate very nicely the appearance of the patient when improvement had commenced, and still later on when in a condition of convalescence.

MEDICAL PROGRESS.

SURGERY.

The Treatment of Tuberculous Peritonitis.—With the facility with which surgeons enter the abdomen comes the question whether they have not overreached their abilities to do real good in some conditions. C. FENGER, in speaking of the operative treatment of tuberculosis of the peritoneum (Ann. of Surg., Dec., 1901), says that the difference between a laparotomy and a puncture, with regard to its effect on the exudate, is probably more apparent than real. From the nature of the disease it seems that the termination of its progress is the main factor in the improvement. It is immaterial, therefore, by what method evacuation is secured. The frightfully disappointing results of radical surgery in peritoneal tuberculosis, curetting, excision of tuberculous tumors in the omentum, the breaking up of adhesions and the removal of mesenteric glands must teach us that Nature cures tuberculosis of the peritoneum better than the surgeon, and it seems well established that, as Borchgrevink puts it, serous tuberculous peritonitis is a territory which surgeons must hand back to the internal medical clinic with thanks for the splendid opportunity which a misunderstanding gave to the profession by means of laparotomy to study tuberculosis in one of the large cavities of the body.

Peritoneal Tuberculosis.—The diagnosis of this disease differs in children and adults. The points to be remembered in children, says D. N. EISENDRATH (Ann. of Surg., Dec., 1901), are abdominal symptoms, namely, distention, pain, disturbed action of the bowels, presence of fluid and emaciation, with irregular fever. If the ascites is sacculated instead of diffuse, the diagnosis is still more easy. Cirrhosis of the liver is rare before nine years of age and occurs usually in syphilitics, with more or less jaundice. Irregular tumors may be present and chronic abscess opening at the navel is suspicious. Family history may aid. In adults, without an exudate, the diagnosis can even be made from the presence of a single or many irregular tumors of the omentum. Multiple carcinoma must not be forgotten and transverse tumor of the omentum must be distinguished from tumor of the stomach. Tumors posterior and lateral to the uterus with symptoms of slow inflammation always suggest tuberculosis by the rapid growth of the effusion; coincident pleurisy, greater degree of gastro-intestinal disturbance, irregular hardness along the edge of the tumor are distinguished from cysts of the ovary. With the cervix drawn and held, a bimanual examination through the rectum and the abdomen would distinguish a cystic tumor if connected with the cervix and an ovarian cyst by its pedicle. Occasionally tubercle bacilli appear in the curettings. When the ascites is free we distinguish it from that due to cirrhosis of the liver by the presence of alcoholism or the history of syphilis and by the character of the fluid withdrawn. Cirrhosis of the liver and tuberculosis of the peritoneum may occur in the same patient and then render diagnosis very difficult. Similarly, non-tuberculous and true tuberculous peritonitis are always impossible of certain distinction. When the family history is good and there are no signs of tuberculosis elsewhere, no tenderness or excessive amount of fluid, the chances are that the case is non-tuberculous.

Tuberculous Appendicitis.—This is a well-known though an uncommonly recognized form of appendicitis. E. W. ANDREWS (Ann. of Surg., Dec., 1901) considers that it must be distinguished from all th-

other forms of appendicitis, from exudate and residuum, from diseases of the adnexa, from intussusception, from actinomycosis, and from carcinoma and sarcoma. Of these but two among the various forms of appendicitis and malignant disease of the cecum are very common and no distinction can be drawn in many cases until the abdomen is opened. The treatment in important cases is in the nature of an emergency operation. Its phases are as follows: (1) Laparotomy for simple exposure, as in other forms of tuberculous peritonitis; (2) excision of masses in the omentum with breaking up of the adhesions; (3) artificial anus; (4) partial removal of the whole of the cecum or plastic operations thereon; (5) lateral anastomosis or partial exclusion; (6) resection of the cecum with end-to-end anastomosis or total exclusion. This last method has been repeatedly done and is certainly an ideal manner of dealing with tuberculous and cancerous tumors in or immediately about the cecum. The mortality is 16¼ per cent. for all of the aforementioned methods of operation.

Obturator Hernia.—The operative treatment of this rare form of hernia must be considered under two heads, which R. J. Gladstone (Ann. of Surg., Dec., 1901) calls the intra- and extra-abdominal methods. Exploration is practically the aim in all these cases. Some complications of the rupture may easily be reached without opening the abdomen, but probably the difficulties of the case will justify such a step. The external operation has the great disadvantage of a dangerous proximity to the large vessels of the lower extremities and furthermore a deep, narrow field. The intra-abdominal method, on the other hand, through a median incision low down, avoids all of these conditions and adds the advantage of making an artificial anus in the lower part of the wound in cases of strangulation. In the anatomy of this form of hernia it must be remembered that it never receives any covering from the pelvic fascia, because the proper line of attachment of the obturator portions of this fascia passes below the obturator canal, where it forms the lower boundary of this passage by blending with the upper border of the obdurator membrane. The second point of anatomy is that the obturator artery divides and the two branches of the obdurator vein unite immediately below the sac; hence, in cases of strangulation of the hernia, great care must be exercised in dividing the tissues. A single, free, downward and inward cut would almost certainly divide these vessels.

Duodenal Ulcer and Its Surgical Treatment.—The cardinal symptoms of duodenal ulcer are pain, hematemesis, melena. Its chief complications are profuse hemorrhage, perforation (acute, subacute or chronic), cicatricial contraction, and its sequelæ, periduodenitis, cancer. In 20 fatal cases 9 patients died of hemorrhage, 8 of perforation and 3 of cicatricial contraction of the duodenum or bile-duct. The symptoms of acute perforation, as described by B. G. A. Moynihan (The Lancet, Dec. 14, 1901), are sudden, overwhelming pain, rigidity and tenderness of the abdomen, profound collapse. After the first shock has passed, the symptoms and signs of gastric and duodenal perforation differ in their development. In gastric perforation the signs are those of general peritonitis; in duodenal perforation the course taken by the extravasated fluid leads to a more acute and an earlier involvement of the peritoneum on the right side and in the right iliac fossa. The clinical picture of appendicitis is copied with such accuracy that in 49 recorded cases tabulated by Moynihan, in 18 the first incision was made over the appendix after a diagnosis of acute appendicitis had been made. The medical treatment of duodenal ulcer should be carried out with the same care as in treating gastric ulcers. Surgical treatment may be called for (1) when an acute ulcer perforates; (2) when subacute or chronic perforation leads to periduodenal or subphrenic abscess; (3) in chronic ulcer when pain and gastrorrhagia or enterorrhagia are persistent and disabling; (4) when cicatricial contraction and induration or periduodenitis have caused narrowing of the caliber of the gut and dilatation of the stomach.

Extent of Permissible Resection of the Intestines.—How much and what portions of the intestine can be removed without endangering health and life? This question can be answered either by animal experimentation, by records of operated cases showing the later condition of the patient, or by experiments in metabolism in human subjects following intestinal resections. In endeavoring to answer the question A. Albu (Berl. klin. Woch., Dec. 16, 1901) calls attention to the more or less definite ratio between body-length and length of intestine. Beneke reckons 387.5 cm. of small intestine (omitting duodenum) for each 100 cm. of body-length. Estimating the length of the intestine in this wise (for the surgeon cannot measure the intestine even when it is exposed), Albu believes that to remove more than a third of the small intestine is to render impossible the proper nourishment of the patient.

Surgery of the Urinary Organs.—Eleven cases of nephrectomy for tumor in young children are discussed by T. R. Jessop (The Lancet, Dec. 14, 1901). Nine of these patients were operated upon by the lumbar route, which route the writer regards as applicable in all cases in which the tumor can be brought whole through the lumbar incision. While nine subjects recovered, the longest survivor lived scarcely two years and a half. In only three instances was there an opportunity to see the child near the end and in each of these there was undoubted evidence of recurrence. These results being neither better nor worse than those reported by other surgeons, Jessop is not disposed to recommend strongly the operation of nephrectomy in children suffering from malignant growths of the kidney. The difficulty lies in making an early diagnosis; the only prominent signs of the disease in young children are the presence of a tumor and the occurrence of hematuria. The latter sign unfortunately is not constant and when the former sign is present the disease is already far advanced. Nephrectomy in adults gives better results; in most cases the operation is performed for conditions other than malignancy, and even in malignant disease the degree of malignancy is less and the liability to diffusion and return is diminished. Jessop cites six cases of renal tumor in adults, with two recoveries and four deaths after operation. A typical case of recovery was that of a man, aged fifty-six, whose chief symptoms were frequent micturition, hematuria, and a dull aching pain in the left loin, this region being filled by a large growth; pallor and loss of strength were marked. Statistics which merely compare the percentage of recoveries in nephrectomy by the transperitoneal route with that of operations by the lumbar method are misleading; the least promising cases (those presenting the largest tumors) are the ones usually approached transperitoneally. It is, however, important to remember that in the transperitoneal route the peritoneum is twice incised, while in the alternative operation this membrane is not necessarily wounded at all; this consideration is of prime value in cases of suppuration, the lumbar route being imperative in such cases, as also in all cases which present no such difficulties as are due to the mobility of

the organ to be removed or to its extreme size. In performing nephrolithotomy in five cases by the method of Henry Morris, Jessop had no difficulty in controlling hemorrhage and no subsequent urinary fistula. In dealing with stone in the bladder the choice lies between litholapaxy and suprapubic lithotomy; in a perfectly-uncomplicated case the former is preferable as involving less mutilation and a briefer convalescence. But litholapaxy is negatived by advanced stricture of the urethra, advanced prostatic disease (here the suprapubic operation affords the additional advantage of dealing radically with the prostate), pronounced cystitis of long standing, encysted calculus, calculi too large to be crushed. Perineal lithotomy is considered by Jessop to be all but relegated to the past.

Surgery of the Mediastinum.—Operations about the large structures of the body, especially those of the chest, are rather new in the domain of surgery. The following conclusions are arrived at by Prof. ENDERLEN (Deut. Zeitschr. f. Chir., Nov., 1901). The position of the esophagus is highly variable even in the normal subject, with reference to the spinal column or leaves of the pleura, particularly on the right side, and to the aorta. The approach to the esophagus is most convenient on the left side if above the level of the bifurcation of the trachea, on the right side if at the level of the fifth or sixth thoracic vertebra, and again on the left side if from this point downward as far as the diaphragm. On the whole, the best form of incision is either a curved or a rectangular one with the base directed toward the spinal column. The application of operations on the posterior mediastinum is very limited and, with respect to the final safety of the patient, should be assigned particularly to foreign bodies which cannot be removed by any other and safer means, or which have certainly perforated the esophagus, and also to the cure of that rare form of diverticulum in the lower part of the esophagus, which usually defies all palliative treatment and cannot be induced to close by means of adhesions. As a primary aid to an operation upon the esophagus in this region gastrostomy must be done. Clean cut wounds of the esophagus can usually be sewed and heal promptly. Otherwise packing and secondary healing must be resorted to. Wounds of the pleura during operation must be closed first with packing while the operation is in progress and later can be sewn up. Further application of the operation of posterior mediastinotomy concerns abscesses which have their origin in the bones of the spinal column or ribs, or in the esophagus itself. Finally lung abscesses localized in this region may be approached through this channel.

X-Ray Burns.—With the value of the X-rays as a means of diagnosis there has been found the danger of causing certain forms of skin trouble after prolonged exposure. T. W. HUNTINGTON (Annals of Surgery, Dec., 1901) reviews this subject and states that the usual process is subacute or chronic necrobiosis. The cause of this death of skin-tissue depends upon an irritation of the peripheral sensory nerves, with a secondary paralysis of the vasomotor system of the affected area. Spasmodic contraction of the small blood-vessels follows. Nutrition of the cells is impaired and then their death becomes the logical result. A peculiar, progressive gangrene has been known to appear four weeks after exposure. It began in the center of the affected area and did not invade the outer limit until after four months. During this whole time there was persistent, though almost imperceptible, progression. It was found that the intima of the arterioles and veins, especially of the latter, was much thickened, and that the lumen of all was correspondingly narrowed. This, it is claimed, was due to a deposit of reticular masses of delicate fibrous tissue. Similar processes were noted also in the other coats of the blood-vessels. The deeper vessels continued to perform their function imperfectly and later indicated a degenerative process also. Authorities generally agree that medical treatment of these ulcers is not at all satisfactory and usually altogether useless. From the standpoint of surgeons it must be borne in mind that a slowly-progressive degenerative process is the essence of the disease, which both superficially and vertically is without definite limitations. Symptoms attributable to hyperesthesia of the affected area are of some value, but evidence referable to this source is unreliable, owing to tardy encroachment upon what had seemed previously to be healthy tissue. It follows therefore that if the ulcer is to be excised the operation be performed with extreme boldness to the end that all tissue supplied by defective blood-vessels may be removed.

Galvanocautery and Circumcision.—The various means of doing this small operation seem without end. S. LEDUC (La Sem. Méd., Dec. 4, 1901) brings out the method of using the galvanocautery instead of the knife. The steps of his operation are briefly as follows: Perfect anesthesia is first produced by a 1-per-cent. solution of cocaine. The prepuce is then seized in two clamps whose points approach each other at the root of the frenum in such a manner that each includes a triangle whose base takes in the lower third of the preputial orifice and whose apex corresponds with the root of the frenum. With the galvanocautery this tissue is then cut away. A dull red heat of the instrument is necessary. A third clamp is now placed so as to remove whatever more is necessary. If the temperature of the instrument has been correct the wound does not open and there is no bleeding. The operation can be done rapidly and very safely. The only dressing necessary after it is a covering of ointment with a low percentage of some antiseptic like salicylic acid or red precipitate in it. The patients as a rule can continue their vocation without interruption. The method has the advantage of uncovering the glans of the organ perfectly and also of giving the least possible deformity. Occasionally, if the temperature of the cautery has not been properly regulated, the lips of the wound will spread. Healing takes place by granulation and is usually slow, but even then the final result is good.

Hepatic Drainage.—Attention is called to the analogy between gall-bladder disease and appendicitis and the necessity for early diagnosis and treatment by J. B. DEAVER and E. K. MOORE (Phil. Med. Jour., Dec. 21, 1901). Gall-bladder disease is very protean in character, probably more so than appendicitis. Like the latter it is a progressive inflammation with successive periods of latency and of acute exacerbations which may at any time prove serious. Gall-stones play the same part as fecal concretions, causing ulceration and stricture of the ducts. The symptoms caused by catarrhal inflammations vary widely. When the swelling of the mucosa of the ducts is not sufficient seriously to impede the flow of bile, the only symptoms are a slight enlargement of the gall-bladder with a little local tenderness, a slight rise of temperature, some malaise and anorexia. Severe grades have more alarming symptoms of obstruction and colic. The diagnosis of pericholecystitis is more difficult and confusing. Adhesions to the duodenum may cause dilatation of the stomach, adhesions to the transverse colon or other parts of the intestine symptoms of intestinal indigestions, and adhesions to the stomach may closely simulate gastric ulcer. Probably many cases of chronic dyspepsia and intestinal indigestion are caused by the

adhesions of cholecystitis and appendicitis. In general it may be said that the symptoms of gall-stone disease are occasioned either by the pericholecystitis or by defective drainage. The symptoms of the former may be relieved by freeing the adhesions, but the prevention of their reappearance lies with their cause, the defective drainage of the gall-bladder and liver. In early cases before any anatomical changes have occurred, temporizing and the Carlsbad Sprudel treatment are indicated, but when adhesions and strictures are present waiting is dangerous. When during an operation a marked change is found to be present in the gall-bladder, its removal is indicated, for this insures freedom from the disease and adds little to the gravity of the operation. It has been proved that as an organ it has very little function in man. Fistulæ are done away with and the seat of the beginning of most cases of defective drainage is removed.

THERAPEUTICS.

Orthoform in Syphilis.—Orthoform has been known for some time as a local anesthetic. More lately it has been used for internal administration. A. Einhorn and R. Heinz, who discovered the product, have successfully given it for the pain of round ulcer and cancer of the stomach, admitting however that the drug does not act unless the continuity of the mucous membrane is broken, that is, unless it becomes a local anesthetic. BOUVEYRON and SIRAUD (La Sem. Méd., Dec. 4, 1901) have been administering orthoform in a total daily dose of two to three grams, divided into four to six powders, with success against the essential headache of syphilis. Most frequently, the smaller dose, namely, two grams in twenty-four hours, is sufficient to quiet all this rebellious pain. Usually a decrease takes place during the first night and after that the pain disappears entirely. In order to avoid recurrence it is necessary to continue the drug several days. The precise method of employing the drug necessitates a distinction between continuous and intermittent headaches. For the intermittent headaches the best method is to take a powder containing 0.50 gram of the drug about one hour before the expected time for the pain to appear and two similar powders during the latter part of the night. For the continuous pain, four such powders should be given at regular intervals; for example, every six hours. Sometimes the ingestion of this drug provokes a sensation of heat or irritation in the stomach, which may be corrected by giving an equal quantity of sodium bicarbonate with each administration. On the other hand orthoform does not quiet in any degree the dysphagia of syphilitics or other pains in the thorax, periosteum or vital organs.

Cocaine in Morphine-Poisoning.—A case which is interesting from several standpoints is reported by A. C. BARNES (Phil. Med. Jour., Dec. 21, 1901). A girl was employed in handling finely-powdered morphine sulphate. After a few hours the symptoms of typical morphine poisoning of a very severe type set in, with pronounced cerebral, respiratory, and cardiac depression. The usual restoratives were applied without much effect. Because its primary physiological activity is that of a descending stimulation, cocaine was then employed. One-half grain of the hydrochlorate was given hypodermically and repeated in half an hour. Although almost moribund, the patient ten minutes later showed signs of returning consciousness, with increased pulse and respiration. As this did not seem sufficient, another quarter of a grain was given. This, however, was followed by signs of cocaine poisoning which subsided in a few hours, but were succeeded by stupor with slow pulse and respiration. The latter condition was successfully combated with coffee, forced exercise, etc., and the patient made a complete recovery from the effects of the poisons. Care must be exercisd in giving the cocaine—half a grain at half-hour intervals until consciousness returns and the respiratory and cardiac functions are sufficiently aroused.

Urosin in Gout.—For all cases of acute gout, but also in the subacute and chronic forms and in arthritis deformans, J. HONIGSCHMIED (Wiener med. Blät., Dec. 19, 1901) has found in urosin, the quinic acid salt of lithium, a remedy which rapidly alleviates and in the majority of instances cures unless marked anatomical alterations exist in the joints. No bad after-effects were noted even after large doses. The usual administration consists in giving three pastiles during the acute stage, to be repeated in one hour if there is no relief. After this, about ten may be given daily for some time.

Administration of Phosphorus in Cod-liver Oil.—A great disadvantage in combining the peculiar action of phosphorus with those of the fatty oils, most particularly cod-liver oil, has been the slight stability of the solution. To render it more permanent K. DIETERICH (Therap. Monatshft., Dec., 1901) recommends using oils supersaturated with carbonic acid gas as solvent. A number of experiments showed that, if ordinary phosphuretted cod-liver oil is preserved for six months, it loses in strength up to 50 per cent.; with the oil saturated with gas the difference is so slight as to be unimportant, even if the bottles are kept without stoppers. Another advantage in the use of these oils lies in the fact that they do not readily take up oxygen and hence, by not becoming rancid, retain their pleasant taste.

Serumtherapy in Diphtheria.—Serumtherapy is not an old method of treating disease, therefore the question of its ultimate influence upon disease is still a somewhat unsettled question. D. DE MAURANS (La Sem. Méd., Dec. 11, 1901) gives an exhaustive review of serumtherapy in diphtheria, based upon statistics drawn from the reports of the Boards of Health in the chief cities in Europe from 1883 to 1900. He notes that prior to the first use of serum in 1895 the disease underwent periodical changes in virulence, so that the range in mortality in a given city was highly varied. During this period, for example, in Hamburg, in 1883, the reported deaths were 360; in 1887, 650; in 1891, 250; in 1894, 420; in 1895, 140; in 1896, 100. Independently, therefore, of the use of serum this one city indicates a wide variation in the death-rate. The last two years were, however, just after the new method was introduced. This same periodicity is present also in other infectious diseases. While he does not claim that serumtherapy is without effect upon the disease or that it is not the very best method of treatment which we possess, all factors considered, he does raise the question as to whether or not the vast improvement in the death-rate as given in the reports from 1895 up to the present may not be due to the fact that we have, during these years, been living in a time of moderate virulence of the disease. In support of this supposition he points out that in Paris from December 31, 1900, to November 30, 1901, a very rapidly-progressive increase in the death-rate had been present, from 300 to over 600. The question is certainly an interesting one, but the paper seems to lack a true scientific basis because it treats solely with the bare numbers of deaths reported, without any reference to the basis of the diagnosis, bacteriological or clinical, upon which the reports rested; to the presence or absence of mixed infection; to the seat of the disease, whether localized in a certain part of the throat or widely dissem-

inated through the upper air-passages; or to the causes of death, whether from the disease itself or from its complications or its sequelæ. Without due regard to some or all of these problems any such review will certainly lack the highest scientific grounds.

Treatment of Bright's Disease.—In discussing the treatment of this disease, J. W. BRANNAN (N. Y. Med. Jour., Jan. 4, 1901) enumerates in general terms the restriction of the proteid diet, the prohibition of strong alcoholic drinks, the free use of diluents, especially alkaline mineral waters, and the promotion of the action of the skin and bowels. The white meat of chicken and fish should be placed upon the same basis as the red meats, the only difference being the small amount of blood in the white meat. Von Noorden prescribes small quantities of both kinds of meat. Beef extracts are really worse than is the whole meat for they contain the irritating principles in a concentrated form. As causes of acute Bright's he refers to only two, scarlet fever and exposure to cold or wet, the former being the most frequent cause in children, the latter in adults He has noticed that acute nephritis seldom occurs in his Bellevue Hospital service, but in private practice exposure seems to be a rather common cause of this disease in adults. He alludes to the possibility that the hospital patients are more accustomed to exposures and hence less liable to sustain injurious effects from them

Erysipelas and Leprosy.—Observation of two cases of leprosy which were greatly improved after an attack of erysipelas leads A. PATRON (Gac. Med. d. Mexico, Dec. 15, 1910) to raise the question of immunity to a virus by inoculation with an attenuated form of the same virus, as in the treatment of diphtheria, or with that of another specific infection. The bacilli proteus vulgaris and prodigiosus, as well as the bacillus of Eberth, have created a state of resistance to Asiatic cholera. Cures through the influence of erysipelas upon other diseases have been noted by various observers, among whom may be mentioned Bazin, Kaposi and Wolkman, who reported improvement in lupus after the onset of erysipelas; Langenbuch cites a cure of multiple sarcoma of the skin by erysipelas migrans; Muir witnessed a rapid cure, through the influence of erysipelas, of articular tuberculosis of the arm of fourteen years' duration, in which bacteriological examination had shown Koch's bacillus in quantities. All other remedies had failed to influence the condition. The author asks the coöperation of bacteriologists generally in the study of erysipelas as a curative agent, especially in leprosy, which is on the increase in many parts of America, and for which there is no cure or remedy which will stay its progress. The query is put, "Can scientific inoculation of the streptococcus erysipelatis or its toxin be used in the treatment of this disease without injury to the patient?"

PEDIATRICS.

Hypodermoclysis in Pediatrics.—A large field for this method of treatment is still open in the field of children's diseases. W. C. HOLLOPETER (Phil. Med. Jour., Dec. 7, 1901) states that its usefulness is most marked in hemorrhages of the newly-born from genitals or umbilical cord, in purpura, in marasmus, in the toxemias associated with the acute eruptive fevers, in anuria due to uric-acid infarcts, in shock, in syphilis, and in tuberculosis. The technic is briefly as follows: A sterile normal salt solution is used which must be delivered to the tissue at 106° F. The gravity bottle or a large hypodermic needle is employed. The latter is preferable, especially in young children. The best site is over the great trochanter, although the inside of the thigh may be used. Sufficient anesthesia can be secured by a lump of ice or an ether spray. From one to two ounces of salt solution can be used at a time and from five to ten minutes should be consumed in the act of injecting it into the subcutaneous areolar tissue. In such cases in which the body is overwhelmed with fluids and toxins, as in acute nephritis, the hypodermoclysis should be preceded by a glycerin enema, which quite effectively drains the tissues, a more rapid entrance being thus provided for the subcutaneous injection.

Whooping-Cough.—This disease, so difficult of treatment, is the subject of a long article by E. WEILL and M. PÉHU (La Sem. Méd., Nov. 27, 1901). Their conclusions as to the management of whooping-cough, especially in children, are as follows: The essential is to arrest efficiently and conveniently by any means the symptoms of the disease. Such means must be easily applicable to the child. It must be remembered that the affection is cyclic and that the duration of the attacks of coughing is rather definite. The period of the disease in which treatment must be begun is all important, but unfortunately the record of the fact as to the period of beginning treatment fails in all statistics. Another point in which statistics are deficient is how often the disease attacks patients in a hospital compared to those in private practice. In hospitals apparently contagion often leads to bronchopneumonia and to tuberculosis. It seems, therefore, that on the whole the present method of making statistics of this disease does not rest on a firm foundation. As to the actual medication in whooping-cough, two distinct indications must be met, namely, to diminish the number of attacks and to prevent infection of the bronchi. It is necessary as far as possible to leave the digestion undisturbed and therefore all medicines which tend to derange it, as, for example, quinine, should be used as little as possible. Furthermore, all drugs which may develop poisonous effects should be discarded. Bromoform is a clear example. Antidiphtheritic serum must also be condemned on account of the unfavorable symptoms which it occasionally provokes. Lastly, the medicine used must not cause the child any irritation, anger or disturbance of the nervous system. Those procedures which may be in themselves rational, but which necessitate a good deal of machinery, are always difficult to carry out on account of frightening the child. Such are intralaryngeal instillations and the various local applications of antiseptics and sedatives to the throat. Inhalations of all kinds, however, are much better. The best of these is quinolein, a derivative from coal tar, in the form of the tartrate, up to the daily dose of 0.25 cg. to 1 gm. About 100 cubic centimeters of water are taken and from 10 to 20 drops of quinolein added to it for each child under treatment. The children of the household or institution are shut in a closed room three or four times a day, where during five minutes at a sitting they are subjected to steam laden with this drug. All of the above indications are met and difficulties surmounted by this method. On the other hand, it must not be assumed that this method is a true specific for whooping-cough, but it is a very convenient and efficacious remedy.

Tuberculous Peritonitis.—In a clinical lecture, A. CAILLÉ (Pediatrics, Dec. 15, 1901) presented a girl, four years old, who showed a large liver and spleen and an abdomen distended and tense and dull from the umbilicus downward. The urine obtained by catheter was free from albumin, sugar or bile. The percussion dulness does not change with the child's position, and the fluid is therefore contained in the interstices of the intestine matted together by adhesions. This and the

distention, pain, disturbed bowel action and loss of weight, with an irregular rise of temperature, point to tuberculous peritonitis. Non-tuberculous serous peritonitis usually has free fluid. Paroxysmal pain in the abdomen in children is also often due to worms, intestinal indigestion, membranous enteritis or chronic appendicitis. The author distinguishes four varieties of tuberculous peritonitis, viz.: (1) chronic miliary with ascites; (2) fibrocaseous; (3) fibro-adhesive; (4) tuberculous peritoneal tumors. Spontaneous cures have been reported and good results have often followed opening the abdomen when the infection is limited to the peritoneum. Medical treatment is extremely unsatisfactory.

THERAPEUTIC HINTS.

The Bath in Phthisis.—In this condition the patient cannot properly respond to pouring cold water over his skin or dipping him in a cold bath, so SIMON BARUCH (Post-Graduate, Nov., 1901) advises washing him with a bath-glove and gentle friction, a small portion of the body at a time. Take a basin of water at 90° F.; put the patient on one side of the bed; place a blanket and linen sheet under him, and, dipping the hand into the water, rub him on successive parts of the body. At each application reduce the temperature of the water, and, if the fever reaches 102° F. bathe every two or three hours. The parts below the knees and elbows should be skipped, as they do not react well. "Cold water is about the poorest antipyretic I know of," but it is used to stimulate and refresh the nervous system, and thus improve the patient's resisting power. For the hectic fever, tub-baths at 90° F., perhaps reduced gradually to 80° F., with friction, are of great benefit. A good and simple method of educating and disciplining the nerves and blood-vessels of the skin to bear colder and colder water and greater and greater force, with a fruitful reaction, is to throw forcefully six to twelve dipperfuls of water at 85° F. daily over different parts of the body. There is no danger of taking cold after these baths.

Diet in Tuberculosis.—A diet for tuberculosis is arranged by M. EINHORN (Post-Graduate, Nov., 1901) as follows: Breakfast at 7.30 a.m., two eggs, toasted bread and butter, coffee, with half milk, sugar and cream. A glass of milk or kumyss, bread and butter at 10 a.m. Lunch at 12.30, meat (steak, chicken) mashed or baked potatoes, white bread and butter, cup of coffee with milk and sugar. At 4 p.m. the same as at 10 a.m. Dinner at 7 p.m., meat-soup, with a little rice or farina in it, meat, mashed potatoes, rice or green peas, or any other light vegetable, bread and butter. Oysters, crackers and butter, a glassful of ale or stout at 10 p.m. The diet should be carried through whether there is appetite or not.

Early Care of Deaf and Dumb.—When the deafness is detected, generally by the child's failure to learn to talk, the parents should talk to the child the same as before. They should encourage the child to watch their lips and their gestures and have him, as he gets older, feel with the hand the current of air issuing from the mouth as they talk, and the coincident laryngeal vibrations. Common objects should have labels affixed to them in plain print. Later he should be shown the names alone, and asked to point out the objects. The deaf-mute should be taught to dress, wash and feed himself, should have toys, and behave the same as other children. But he has a tendency to irritability and loss of self-control. Music, the soft answer, the good-humored chaff are without effect upon him, and he is often made worse by ill-judged punishment.—W. B. DRUMMOND in Pediatrics, Dec. 15, 1901.

Treatment of Pulmonary Tuberculosis at Home.—The first order given by LEONARD WEBER (Post-Graduate, Nov., 1901) in early cases is to rest in bed till the temperature is practically normal. The bedroom is made to conform to those in a hospital by simple furniture, frequent ventilation, and plenty of light. The sputa are collected in spittoons containing a five-per-cent. solution of carbolic acid, or three-per-cent. formaldehyde, or in paper boxes which are burned. Food is given in small quantities and more often than usual. During acute fever the patient is sponged with alcohol and water three times daily, and, when improved, takes a cool sponge-bath every morning. Keeping down the high temperatures saves strength and body-weight, and to do this the author uses

℞ Acetanilid ..... 0.06 (gr. i)
Phenacetin ..... 0.2 (gr. iij)
Antipyrin ..... 0.2 (gr. iij)

Hemorrhage is treated by ice application to the chest in the form of two small ice-bags, one below each clavicle, dry-cupping and the internal administration of a teaspoonful of table-salt two or three times the first day, codeine, gm. 0.015 (gr. ¼), and from the second day fluid extract of arbor vitæ, c.c. 4.0 (ʒi), three times a day. The general irritability, harassing cough, etc., should be treated for a week or two as an acute bronchitis, a valuable remedy being

℞ Aq. chloroformi ..... 180.0 (ʒvi)
Sodii bicarb. ..... 4.0 (ʒi)
Morph. sulph. ..... 0.06 (gr. i)
Aq. lauro-cerasi. ..... 4.0 (ʒi)

M. Sig.: Four to eight cubic centimeters (ʒi-ij) in water every three hours. When this acute stage subsides, creosote treatment may be begun. The creosote capsules have not proved so good as has the solution in an equal volume of alcohol. The patient begins with ten drops of this in half a tumbler of milk or water three times daily, an hour and a half after eating, and doubles the dose each week up to sixty drops. Dry cough may be met by codeine sulphate, weakness by strychnine, weak hearts by cardiac tonics.

The Hemorrhagic Diathesis.—In presenting a child of a "hemophiliac" family, who had bled for five days from a wound of the mouth, and whose bleeding was checked by the actual cautery after stypticin, used locally and hypodermically, had failed, A. CAILLÉ (Pediatrics, Dec. 15, 1901) calls attention to the successful use of alum solution, 10-per-cent. antipyrin, or adrenal solution. Some surgeons give gm. 0.3-0.6 (gr. v-x) of chloride of calcium internally three times a day before operating on one with hemorrhagic tendencies; for instance, in gall-stones with cholemia. In the new-born, persistent hemorrhage from navel, stomach or intestine is met with. The navel can sometimes be effectively transfixed. The author has no knowledge of recoveries of newborn children after they have lost a pint of blood.

Ophthalmia Neonatorum.—To evert the lids and get eye-drops thoroughly in contact with the eye tissues is a difficult matter, which D. C. BRYANT (Western Med. Review, Oct. 15, 1901) prefers not to intrust to the mother. He does this himself, letting the parents wash out the eye several times a day with potassium cyanide solution, 1:8,000, and apply ice to reduce the swelling. He recommends the aseptic irrigator shaped like an ordinary gravy-dish, which is much used in England.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JANUARY 18, 1902.

THE CHARITIES OF THE STATE.

THE recommendations made by Governor Odell in his second annual message to the Legislature, concerning changes in the management of the State charitable institutions, strike one as being almost radical enough to be revolutionary. In the first place, the Governor recommends that the Boards of Managers of the State Hospitals for the Insane be abolished, and that these hospitals be placed wholly under the jurisdiction of the State Commission in Lunacy, located at the Capitol in Albany.

We are unable to believe that this proposition is a good one, for we fail to see what benefit could possibly come out of such a change. On the other hand, we feel that too much centralized power in Albany in charitable matters is a bad thing. There seems to be but one thing it would be helpful to, and that would be the injection of politics in the care of the insane. The Boards of Managers under whose supervision the institutions are now placed are appointed by the Governor, by and with the advice and consent of the Senate and serve for variable periods of time. There has been no occasion to feel that such appointments are now political in nature, for the very good reason that they carry with them no political prestige or power, and no pay. To abolish them and place the management of the institutions in the hands of a central board in Albany, which central board is subject to change at the pleasure of the Governor, would invite, if not force, the care of the State Asylum work into the hands of Albany henchmen.

The proposal to abolish the Boards of Managers of the other charitable institutions, including the reformatories, those for feeble-minded, the blind, the deaf, the dumb and epileptics, is, in our judgment, equally as wrong, and we hope the Legislature may see it so.

To run these institutions, that are now under the general supervision of the State Board of Charities, it is proposed to have a superintendent appointed from the members of the present State Board of Charities, "or otherwise," subject to the approval of the Governor, and who will work under rules and regulations made by the State Board of Charities, which rules and regulations shall also be subject to the approval of the Governor. One can see at a glance that the enactment of such a measure would at once place all the charitable institutions under the entire control of the Executive of the State, and so make it possible for them to undergo complete changes with every change of party. This would be dangerous; it smacks too much of practical politics; and any such proposition should be defeated.

New York State has built up a magnificent system of State charities, and it has taken a long time to do it. This system should not be ruthlessly torn down for the purpose of making fuel to help run the political machines. New York State is rich, its charity requirements great, and large sums are needed to care properly for her vast army of insane, feeble-minded, deaf, dumb and epileptics. If she is spending too much money, or not spending it in the right way, a halt should be called and due economy should be exercised; but do not let us sanction the conversion of this part of the State's work into a part of its political machine. New York City has been so long under the control of the Squire of Wantage as to make foreign control a stench in the nostrils of honor-abiding folk. The control of the State charities at Albany is a step in the wrong direction in that it totally subverts the now excellent plan of local supervision and control.

We shall watch with interest the progress that any bill introduced with the idea of carrying out the Governor's recommendations may make, and we urge physicians generally throughout the State to give the matter their earnest attention.

A PUBLIC HEALTH SERVICE.

In the issue of January 4th of the Medical News we referred to a bill "to increase the efficiency and to change the name of the Marine Hospital Service" which was read before the Senate of the United States, December 19, 1901.

This bill, the Perkins bill, gives the opportunity to establish a National Health Service that, for so many years, has been the dream of the sanitary wise, and we believe that it should be supported along its main lines, if not in all of its present details.

It is unquestionably very sound policy to use the well-equipped Marine Hospital Service as a basis of a National Health Service, rather than to organize a new health service that will either duplicate or render useless much of the work of the already established Marine Hospital Service.

It is to be borne in mind that the present name of the Marine Hospital Service is far from indicating the actual duties of this organization. It more closely fulfils at the present time the office of a public health service and it is not unreasonable that its scope should be widened in order to do so more efficiently. Its enforcement of quarantine regulations, domestic, insular and in foreign ports; its control and management of epidemics; its medical inspection of immigrants, its publication of sanitary reports and statistics relating to problems of public health, and the scientific investigations on medical subjects are all questions bearing most directly and largely on the welfare of the citizens of this country.

Organized, as is the Marine Hospital Service, on a strictly military basis, its discipline, efficiency and *esprit de corps* give the Service a firm foundation on which its accessory duties may be engrafted with benefit.

While it is undoubtedly true that there are a number of details which at the present time seem conflicting with the sovereignty of the State in the control of much of its own health affairs, we believe that once a service is established and the local conditions are appreciated such incongruities can and will be adjusted to the satisfaction of all State authorities.

To bring some order from the chaos of present conditions is desirable, even if such order is not of the most ideal form. What is needed is something to serve as a rational foundation for the establishment of our Public Health Service, and this, we believe, is better subserved by the bill under consideration than by any other which has yet been drafted.

ABSCESS OF THE LIVER.

It was the belief of the elder Flint that abscess of the liver frequently occurred as a complication of the forms of dysentery peculiar to tropical climates, but rarely complicated ulcerative diseases of the intestine in our own climate. This view of the frequency of hepatic abscess prevails to-day in the teaching of our medical schools. To maintain that it is erroneous would be to assume more than we are warranted in assuming at present; nevertheless, it is significant that in the service of a single hospital in New York City twelve cases of abscess of the liver have been surgically treated during the past six months, and we are disposed to raise the question whether the clinical importance of this condition is not generally underrated at the present day.

The subject is of more than theoretical pathological interest, for in the official report of the series of cases just referred to it will be shown that when reasonably early diagnosis is followed by prompt surgical intervention the prognosis is not as bad as might be supposed.

A previous history of intestinal disease cannot be obtained uniformly in cases of abscess of the liver; but, without relying too much on such a history, we may reasonably accept the suggestion of a hepatic focus which it offers in irregular fevers of obscure causation. In cases occurring in New York City a history of typhoid fever is not unusual.

Exploration by means of an aspirating needle is a simple procedure, involving so little risk that it should not be omitted when abscess of the liver is suspected. At best the clinical history of hepatic abscess is obscure; in advanced cases the physical signs are more reliable, but even in such cases a positive aspiration must be depended upon to give the final command for operation.

A febrile movement is the rule in these cases, but too much importance must not be attached to the lack of fever, especially if the period of observation be brief.

Tenderness over the hepatic region, associated with enlargement of the area of hepatic dulness, should arose suspicion. In deep-seated abscesses pain is not a prominent symptom; if perihepatitis ensue the importance of pain is enhanced. When a large abscess exists it is not unusual to notice dulness on percussion over the base of the lung while vesicular breathing is distinctly heard over the dull area, extending to the extreme base. In a routine examination it is customary to look for friction râles over the surface of the liver.

The discovery of such râles will aid not only in the diagnosis of abscess of the liver, but will indicate roughly to what extent adhesions have already formed between the liver and the abdominal wall.

A reconsideration of the subject of hepatic abscess by those who are preparing text-books of clinical medicine would be profitable.

ECHOES AND NEWS.

NEW YORK.

Practical Topics of Inebriety.—Dr. T. D. Crothers of Hartford, Conn., will deliver three lectures in the Hall of the New York School of Clinical Medicine, 328 West 42d Street, New York City, on the following topics: January 21st, "On Inebriety and its Pathology;" January 22d, "Treatment and Cure of Inebriety;" January 23d, "Questions of Responsibility in Inebriety." These lectures will be given in the evening at 8.15 o'clock. Physicians are most cordially invited to attend.

The Osteopathy Bill.—It is evident that the fight against the bill regulating and legalizing the practice of osteopathy in the State of New York, and fixing penalties for the violation thereof, will be fought with more zeal than ever. Senator James H. McCabe of Brooklyn, who is a physician and a member of the Kings County Medical Society, introduced a resolution asking for the discharge of the Committee on Judiciary from the consideration of this bill, and the reference of the measure to the Committee on Public Health.

Gift to the Post-Graduate Hospital.—At the annual reception of the Post-Graduate Hospital, held last week, Dr. D. B. St. John Roosa announced a conditional gift of $100,000 to be applied to the liquidation of the hospital's debt. Dr. Roosa said that the total debt of the hospital was a little under $400,000. The condition attached to the gift is that the remaining $300,000 is to be raised before the $100,000 becomes available.

The American Congress of Tuberculosis.—The Third Annual Session of this Congress is announced to be held on the 14th, 15th and 16th of May, 1902, in the City of New York, in joint session with the Medico-Legal Society.

Smallpox in New York City.—Dr. Lederle has appointed a number of extra vaccinators to cope with this disease, as the signs are that there will be a great increase in the number of cases during the winter.

Maternity Hospital Site.—The directors of the Manhattan Maternity Hospital and Dispensary have selected a plot of four lots, 327 to 333 East Sixtieth Street, between First and Second Avenues, as a site for the Maternity Hospital which is to be built by a wealthy philanthropist as a gift to the East Side poor. It is the intention to provide a hospital, a dispensary and a training school for nurses, housed in a building equipped with every modern appliance. The special features of the hospital will be a corps of doctors and nurses who will care for patients at their homes. The service will be free, although a limited number of beds will be reserved for patients who are not in need of charity.

Manhattan Dermatological Society.—A regular meeting was held on Friday, January 3, 1902, at the residence of the Chairman, Dr. Wm. T. Gottheil.

Dr. R. Abrahams showed a case of *angiosarcoma;* patient previously presented when some doubt was then expressed as to its malignant nature; microscopical sections since made show it to be true sarcoma. The mass occupied the prepatellar region and was about two inches wide by three long. Dr. Gottheil remarked that its tardy growth and the absence of considerable hardness speak against the diagnosis of sarcoma; the diagnosis cannot always be made with certainty without the aid of the microscope. Dr. Weiss accepts the microscopical diagnosis, though admitting the clinical picture was atypical. Dr. Franklin gave a differential diagnosis between granulation tissue and sarcoma as seen under the microscope. Dr. Abrahams further stated that removal of sections was attended by considerable bleeding and shrinkage of the tumor.

Dr. A. Bleiman presented a man of twenty-nine, who showed a macular eruption on chest and dorsum, also large hard papules on the face. The picture of secondary syphilis was considered typical, yet this man shows no initial lesion and denies infection. The diagnosis of *syphilis* was concurred in, Drs. L. Weiss and Gottheil stating that many such cases must be diagnosed irrespective of previous history.

Dr. R. Abrahams presented a man with *Raynaud's disease:* Six years ago there was involvement of the toes of right foot, followed by gangrene and subsequent amputation; later the big toe of the left foot became likewise involved, with loss of the member. At present the process shows itself in the right index finger; the finger is cold and anesthetic, and varies in color from red to blue or white; patient is highly neurotic; diabetes and syphilis were excluded. Dr. Sobel considers the case typical and regards the etiological factor as important. Dr. Bleiman remarked that the trend of opinion seemed to point to the blood-vessels as the primary lesion and reported a case recently observed in which both hands were involved. Dr. Dalton looks for atheromatous changes and regards the blood-vessels at fault. Dr. Pisko spoke in favor of the vasomotor theory.

Dr. Pisko presented a man of twenty-nine years, who gave the following history: Three years ago he complained of pruritis ani; two years ago there appeared on the scalp a hard papular eruption; eighteen months ago on the face and six months ago a red and itchy papular eruption of extensors of forearms. His wife aborted once; she had had five children, four of whom died within the first few months of life. Iodides and mercury did not influence the condition. Drs. Weiss and Sobel remarked that the history might lead on to a diagnosis of *syphilis,* yet they believed that it could be positively excluded. Drs. Weiss and Oberndorfer called attention to the exclusive involvement of the hair follicles and sebaceous glands; they would call it *folliculitis* and *acne;* this diagnosis was agreed upon by all present. Dr. Gottheil called attention to its unusual features. Dr. Bleiman considered it interesting, owing to its chronicity, and Dr. Abrahams called it folliculitis with an accompanying dermatitis. Dr. Pisko looked upon the lesion of the face and scalp as acne varioliformis; that of the hand as cutaneous gumma and that of the forearms as a lesion involving the sweat glands. For diagnostic purposes, sections will be examined and findings subsequently reported.

Dr. R. Abrahams showed a girl of sixteen with a nævus occupying the lumbar region; the mass became embedded in a cellulitis which was further complicated by a *herpes zoster.* The diagnosis of *nævus verrucosus* was concurred in, but Dr. Weiss doubted the coexistence of the zoster; Drs. Sobel and Pisko regard the vesicles as part of the cellulitis. Dr. Gottheil also accepts the latter view and stated that when first seen by him, some time ago, the appearance strongly suggested

zoster. Dr. Fraenkel spoke for removal and Dr. Kinch against such a procedure. Dr. Abrahams further stated that the vesicles followed the course of the nerve and this he deemed conclusive for *zoster*.

Dr. Gottheil presented photographs of a child who for four successive years in the autumn showed some bullous lesion of the leg and foot, situated upon a normal skin. The possibility of pemphigus and other bullous eruptions were discussed.

The following officers were elected for the ensuing year:

President, Wm. T. Gottheil; Vice-President, I. P. Oberndorfer; Secretary and Treasurer, A. Bleiman.

The Old Asylum on Blackwell's Island.—It is suggested that this building be given over to the housing of the tuberculous patients now in the City Hospital. It is now being remodeled and put in repair.

Bellevue Hospital Trustees.—The following names have been suggested as candidates for the seven members of the Board of Trustees of Bellevue and Allied Hospitals, under Section 692 of the Revised Charter: Dr. John Winters Brannan, James K. Paulding, Marcus Stine, Myles Tierney, Samuel Sachs, Howard Townsend, John J. Barry, Charles Macdonald, Felix M. Warburg, Theodore E. Tack, Winslow S. Pearce, Henry R. Ickelheimer, J. Hampden Robb, and Francis C. Huntington.

Infected Milk in New York.—The Commissioner of Agriculture, Charles A. Wieting, has discovered an infected herd of cows at a point about two and a half miles from Peekskill, and, as a result, two cows which have been proved to have tuberculosis have been killed, and the entire herd quarantined, in order to prevent the sale and distribution of infected cattle throughout the State. The milk and products of this dairy were shipped to New York City, and the conditions surrounding the case, the Commissioners said, call for stringent measures. State Veterinarian Kelly and an appraiser from the State Department visited the dairy recently and found it in a deplorable condition. It is owned by a New York City man who knows little of farming. He acquired it six months ago, and since that time about 50 of a herd of 108 cows have died.

Shall Physicians be Permitted to Dispense?—A bill has recently been introduced at Albany amending public health laws by excepting regularly licensed and practising physicians from the prohibitory clause which prevents them from conducting a drug-store, and directing the State Board of Pharmacy to issue a license to physicians who present proper proof that they are legally authorized to practise medicine.

Sanitary Superintendent at Jamaica, L. I.—Health Commissioner Lederle has appointed Dr. Samuel Hendrikson of 46 Bergen Avenue, Jamaica, assistant sanitary superintendent for the Borough of Queens, vice Obed Lusk. The salary is $3,500 a year. Dr. Hendrickson was graduated from the College of Physicians and Surgeons in 1875 and has been in practice at Jamaica for nineteen years.

PHILADELPHIA.

Award of the Gross Prize of $1,000 to Dr. Dawbarn.—The Philadelphia Academy of Surgery, as Trustees of the Samuel D. Gross Prize for Original Research in Surgery of one thousand dollars, have awarded this prize, after six years' interval, to Dr. Robert H. M. Dawbarn of New York. The treatise which won the competition was entitled "The Treatment of Certain Malignant Growths by Excision of both External Carotids." Upon this topic Dr. Dawbarn has worked, as opportunity served, for seven years past. The essay when published will contain the histories, with pathologists' report in each instance confirming diagnosis of malignancy and specifying its variety, of forty carotid extirpations by the author himself; and as many additional by about a dozen other surgeons. At least two of these are members of the Philadelphia Academy of Surgery. By the terms of Dr. Gross' bequest, the prize-essay must be published in book form, and a copy thereof deposited in the Samuel D. Gross Library of the Philadelphia Academy of Surgery.

Smallpox Again Increases.—The record for cases during the present outbreak was broken by the week ending January 11th, when 131 cases were reported The disease is believed to be stamped out at the Philadelphia Hospital and Almshouse, no new case having occurred for nearly two weeks. The inquest held by the Coroner January 11th, in the case of Joseph Goldie, aged eleven years, who was brought here from Bristol in the fall and died from tetanus following vaccination, showed that the real cause of death was "blood-poisoning and tetanus, following secondary infection after vaccination." Witnesses proved that the boy failed to take proper care of the wound after being vaccinated.

Obituary.—Dr. Charles Francis Carpenter died at West Chester, January 5th, in his seventy-sixth year, from influenza. In 1857 he went to Louisville, Ky., where he practised for forty years. During the Civil War he had charge of the Army Hospital at Louisville. Dr. Carpenter was an extensive traveler.

Dr. Alfred N. Mahon, son of Dr. J. B. Mahon of Pittston, died January 11th of nervous prostration following typhoid fever contracted in the Philippines while acting as surgeon on the transport "McClellan."

Annual Exhibition of Pathological Society.—The Philadelphia Pathological Society held its annual exhibition meeting January 9th. These meetings are made very interesting and instructive, members exhibiting gross specimens, microscopic sections, bacteriological findings, etc. As many as fifty microscopes with mounted preparations have been shown by one exhibitor.

Meschianza Too Costly.—The Meschianza held recently in the Academy of Music for the benefit of the McKinley Memorial Hospital Fund was not a success financially, there being a considerable deficit instead of a surplus. The committee made an unfortunate mistake in assuming more expense than it should have done and the fair was not patronized by physicians or the public. The *Press*, in commenting on the affair, says: "The mix-up over the Meschianza now being aired simply proves once more the folly of such elaborate fairs as money-raising projects. The contagious diseases hospital ought to be above such a means of raising the funds needed; in fact, is it not about time that the fair was passed by as an agency for securing funds? It is always a costly, wasteful, unscientific method."

Officers of Academy of Surgery.—The officers elected January 6th are as follows: President, Richard H. Harte; Vice-Presidents, Henry R. Wharton and John B. Deaver; Secretary, William J. Taylor; Treasurer, William G. Porter; Recorder, John H. Gibbon; Council, R. G. Le Conte and W. Joseph Hearn; Business Committee, J. H. Jopson and G. G. Davis.

Accident to Dr. Keen.—Word has been received that Dr. W. W. Keen, who is now in India on his trip around the world, has been unfortunate enough to fracture one of his clavicles, it is reported by falling from a horse. Dr. Keen had his right clavicle broken a number of years ago.

Obstetrical Society.—Dr. John M. Fisher was re-

cently elected president of this Society for the ensuing year.

Smallpox in Pennsylvania.—Dr. Lee, Secretary of the Board of Health of Pennsylvania, has informed the State Health Department that there is an outbreak of smallpox in the village of Shinglehouse, on the borderline between New York State and Pennsylvania. Every precaution will be taken to prevent a spread of the disease.

College of Physicians.—At the meeting of the Section on Medicine, held January 13th, Dr. D. J. M. Miller reported a case of pneumococcic arthritis occurring in a patient suffering from lobar pneumonia. Dr. J. M. Anders exhibited a postmortem specimen of aortic stenosis in which there was a saccular dilatation of the aorta beyond the stenosis at the valves; just beyond the dilatation was a narrowing. The strictly-localized area of atheroma was a point of interest. Dr. Anders stated that the diagnosis of aortic stenosis should never be made unless *all* the signs of that condition were present.

CHICAGO.

National Health Service.—The following resolutions were passed by the American Society of Naturalists and by the Council of the American Association for the Advancement of Science, at meetings held in Chicago during the last week in December, 1901: *Resolved*, That the Council of the American Association for the Advancement of Science approves of the efforts to strengthen the administration and work of the Marine Hospital Service by its establishment as a National Health Service, in the direction of promotion of the public health, the furtherance of scientific investigation relating thereto, and the securing of the cooperation of experts in hygiene and related subjects.

Pavilion for Tuberculous Patients.—At a regular meeting of the Chicago Medical Society, held January 8, 1902, the following resolution was presented by Dr. Frank Billings, seconded by Dr. J. B. Murphy, and unanimously adopted by the Society: *Resolved*, That the Chicago Medical Society petitions the Honorable Board of Commissioners of Cook County to erect a pavilion for tuberculous patients who are gravely ill in the city of Chicago, within practical distance of the center, so as to command the attendance of an efficient medical and surgical staff; and it further petitions that the modern plan of treatment of tuberculous patients who offer hope of recovery be instituted in small cottages located at some suitable place in Cook County. In a discussion on this resolution, Dr. J. B. Murphy said that it was a move in the right direction. Consumptive patients are being treated to-day on an entirely different basis from that of twenty years ago. Seventy-five per cent. of the cases to-day approximately are curable. Furthermore, it is an acute infectious disease, and requires the same guidance, care and treatment that typhoid fever does, and should be treated humanely on that basis. These patients should be housed in an accessible locality, where they can receive prompt and intelligent attention. He offered the suggestion that the pavilion be not attached to the Cook County Hospital. Dr. William Cuthbertson stated that recent investigations have shown clearly the inefficient food supply of patients at the Dunning institution. If this institution for the care of consumptives were removed from Dunning and placed anywhere within city limits, what guarantee would the people or the medical profession have that the patients would be treated any better in the city than at Dunning? He thought it would be better to treat the chronic consumptives at Dunning as they should be treated, and take the money that would be required to build a new institution within city limits and expend it at once in erecting cottages, such as Dr. Billings had suggested, for the treatment of curable consumptives. A large amount of money would be spent in the erection of this building, and he suggested that a competent medical staff be appointed who would be well remunerated for their services and who would be given charge of the chronic consumptives to be treated, and that the money required to build an institution in Chicago should be spent immediately on the erection of cottages.

As to Vaccination and Smallpox.—Dr. Reynolds has issued a supplement to "A Vaccination Creed" noted in last week's issue. It says that not one of the 346 cases of smallpox discovered in Chicago within the last three years was found vaccinated as defined in the "Vaccination Creed." Of the total number, 306 never had been vaccinated at all, though most of them claimed that they had. Examination of the arms proved that these attempts at vaccination were failures; there was no scar and the patients finally admitted that the vaccinations when performed did not "take." A "failure" is not a vaccination; therefore, these 306 cases had never been vaccinated. Of the remaining 40 cases, 26 had old, irregular and doubtful scars said to be the result of vaccination; but these were not characteristic; they were more like the scars from infected sores or wounds than those from vaccine. Nine had fair old scars of vaccinations made from 30 to 40 years previously. Only five had typical (characteristic) scars; but these also were the results of vaccination made many years before and never repeated. In no single case of the 346 had the terms of the First Article of the "Vaccination Creed" been complied with—vaccination had NOT been repeated until it would no longer "take." If it had been they could not have contracted smallpox. These 346 persons are examples of thousands of others who honestly believe they have been vaccinated, because they have had their arms scratched, something rubbed in and a more or less painful sore has resulted. There is no operation so simple and so safe as vaccination when properly performed and cared for. There is no operation in which such serious results follow carelessness and ignorance—even unto death itself, either as a direct result through poisoning of the vaccination sore or from smallpox through failure to secure a successful protective vaccination. It is to be understood that the vaccination herein referred to is that indicated in the Second Article of the "Vaccination Creed," to-wit, that made "on a clean arm with pure lymph and kept perfectly clean and unbroken afterwards." Each one of these points is essential to a protective vaccination and to freedom from serious soreness: The utmost attainable cleanliness; absolute purity of the vaccine lymph; an unbroken surface, by which latter all danger of contamination from external sources—the atmosphere, clothing, soiled hands, etc., is prevented. To be more specific on these points: The arm should be first thoroughly washed with soap and water and the site of the operation then wiped with alcohol. After the vaccine spot has dried, pin a clean soft handkerchief or piece of clean soft muslin to the shoulder-seam of the undershirt so as to hang in loose folds over the spot and prevent the sleeve from rubbing it. This must be changed for a clean one every day until the scab comes off and the surface is healed. The vesicle and resulting scab must not be broken or injured in any way and the arm and its coverings must be kept scrupulously clean from the time of the vaccination until it is well. Because experience has shown that cleanliness and the protection of the surface are best secured by the above method, the Health Department advises against the

use of "shields," bandages, plasters or other dressings; but if these are used—as they are by many physicans—they should only be applied as directed by the physician himself, and with the utmost regard to cleanliness.

Diagnosis of Pericarditis.—Dr. A. R. Edwards read a paper upon this subject before a recent meeting of the Chicago Medical Society. He said that the disappearance of a previously distinctly seen apex beat is very important. Ewart's first rib sign, the separation of the first rib from the clavicle, was described. The strength of the pulse is of value, a strong pulse with disappearance of the apex beat being of marked significance. Under percussion especial emphasis was placed upon the two complementary pericardial recesses of Forber; the first, triangular in form, with its apex directed downward, is found over the base of the heart, and the second in the fourth right intercostal space. Change of dulness observed in the erect posture is also noted in dilated hearts and in valvular heart disease, explained by Sahli by mechanical emptying of the auricles of their blood or by descent in this posture of the diaphragm. Change of the right border of the pericardial dulness in lying upon the right side is important, according to Rosenbach, since this does not occur physiologically. The characteristics of the friction murmur were discussed, especial weight being attached to its superficiality, lack of synchronism with the cardiac activity, its localization (cases being cited in which wide propagation over the whole chest was observed), and the influence of respiration. The friction murmur often persists despite large effusion, in which respect pericarditis stands in contrast to pleurisy. The great frequency with which pericarditis runs a latent course was discussed, as well as the causes of its latency, *e.g.*, severity of symptoms of the primary disease, as rheumatism or pneumonia, the frequently short life of the patient, as a rule, the occurrence of pericarditis as a secondary disease or a terminal affection, and the absence or equivocal significance of the symptoms of pericarditis as noted in the earlier descriptions of the disease. The etiological diagnosis is important, since pericarditis is almost invariably secondary to (1) acute infections; (2) extension by contiguity of inflammation in adjacent parts; (3) cachexiæ or dyscrasiæ. Differentiation was held to rest upon (*a*) the friction, and (*b*) the dulness. After discussion of differentiation from endocardial murmurs, the relation of pericarditis to valvular lesions, hidden by the exudate was considered of great importance and often to be suspected by the character of the pulse, etc. Under percussion, confusion with cardiac dilatation was considered too often inevitable, especially when dilatation of the heart coexisted with hydrops pericardii, hydrothorax, etc. Other evidences of stasis, as hydrothorax, usually antedate the hydrops pericardii. The clinical evolution, effects of digitalis and drastics, the iodide of potash, etc., are of differential value. Pulmonary retraction, mediastinal tumor, aneurism, marginal pulmonary infiltration, callous pleura, anterior mediastinitis, superabundant fat, etc., also received consideration.

CANADA.

Appointments.—Dr. E. P. Benoit has been appointed physician to the Montreal Jail. Dr. G. C. Ferrier, who was graduated from Queen's University two years ago, has been appointed a member of the Canadian Field Hospital for South Africa. Many medical students of the different colleges throughout Canada have also been appointed on this field hospital. Dr. A. T. Hobbs, formerly assistant surgeon at the Asylum for the Insane, London, Ontario, and who is chiefly known to the medical profession for his work while there in connection with gynecology among the female insane, has been appointed superintendent of the "Homewood Retreat," a private asylum at Guelph, Ontario.

Sir William Hingston's Professional Jubilee.—Sir William Hingston, the distinguished surgeon of Montreal, is celebrating his professional jubilee, and his friends and confrères have recently given testimony of their esteem by presenting him with a portrait in oils of himself. Sir William was graduated from McGill University in 1851 and from Edinburgh University in 1852. He organized the first board of health ever in existence in Canada, is a past-president of the Canadian Medical Association, an Honorary D.C.L. of Bishop's University, also LL.D. of Victoria University, Toronto, and a vice-president of the Montreal Branch of the St. John's Ambulance Association. He has also been the recipient of distinguished honor from the Supreme Pontiff, her late Majesty Queen Victoria, and also from the Dominion Government.

Consumption Sanitarium for Calgary.—The Government at Ottawa have received copies of a resolution recently unanimously passed by the City Council of Calgary, N.W.T., which protests against the increasing number of consumptives who are continually pouring into the western city in search of health and benefit from the fine climate. This resolution points out that nearly all of these persons come from the province of Ontario and other Provinces in the east, and therefore, calls upon the Dominion Government to erect a sanitarium in that locality or else contribute aid for the purpose. Should the Dominion authorities decide to comply with this request the Calgary Council will gladly co-operate.

A New Asylum in Ontario.—The old Victoria University buildings at Coburg, Ontario, have been converted into an Asylum for the Female Insane, and on January 4th was formally opened. It has accommodation at present for 150 patients, and the congestion in the other asylums of the Province will be relieved by transporting some of the patients thither. Dr. McNichol of Coburg has been appointed superintendent and he will have associated with him as assistant physician a female doctor, Dr. Cockburn of Toronto, this being the first instance of the appointment of a female doctor to the hospital service in Canada.

Notre Dame Hospital, Montreal.—The annual report of the Notre Dame Hospital, Montreal, shows that the past year has been one of excellent work. During that time there were 2,200 in-patients treated (177 more than the previous year), of whom 1,845 were cured, 155 reported as incurable and 134 died. In the surgical department there were 862 cases; gynecological, 250; ophthalmological, 180. The free medical advices numbered 20,078; in the pharmacy 24,246 prescriptions were filled. The financial report showed that the receipts had been $32,293.35 and the expenditure $29,480.54.

Ontario Medical Defence Association.—A deputation from this Association, composed of practitioners from different sections of the Province, waited on Premier Ross last week at Toronto. This Association desires to see the Medical Council, the governing body of the College of Physicians and Surgeons of Ontario, more representative and their mission on this occasion was to ascertain if the Government would introduce legislation at the present session of the Legislature to remedy so-called evils and thus do away with the appointed and homeopathic representatives, as they claim that the latter have altogether too much influence

in the affairs of the Council. The Premier promised consideration.

Laval University.—This institution will celebrate the fiftieth anniversary of its foundation on June 24th next.

Victorian Order of Nurses.—This order has received $23,000 toward the Cottage Hospitals Fund and of this sum $11,000 has already been disbursed.

GENERAL.

St. Louis Medical Society of Missouri.—This Society held its last regular meeting Saturday evening, January 11th. A paper on "Traumatic Rupture of the Intestines from External Violence" was read by Dr. A. H. Meisenbach.

Association of American Anatomists.—According to *Science*, the officers elected by the Association of American Anatomists are as follows: President, G. S. Huntington, New York; Vice-President, D. S. Lamb, Washington; Secretary and Treasurer, G. Carl Huber, Ann Arbor; new members of Executive Committee, C. A. Hamann, Cleveland, George A. Piersol, Philadelphia, and F. H. Gerrish, Portland, Me.

Infant Mortality in Russia.—The St. Petersburg correspondent of The (London) Times says alarming figures in regard to infant mortality are made public by the medical reports to local authorities. It appears that in many Governments 40 and even 50 or more per cent. of the children die in their first year. The mortality is attributed mainly to the ignorance of the peasants and to the fact that the mothers frequently neglect their children in order to work in the fields. Another cause is said to be the employment of wet nurses, necessitating the feeding of the nurses' children by artificial means. In one Government, where the mortality of infants among the Christians is 342.1 per thousand, the death-rate among the children of Mohammedan parents is 140.4 per thousand. The Mohammedan law compels mothers to nurse their own children.

Weird Causes for Suit.—The damage suit just decided by the Massachusetts Supreme Court against a woman who had brought action against the city of Boston on the ground that she contracted rheumatism as the result of climbing down into a catchbasin to rescue her child, who had fallen through and was drowning in the sewer, was somewhat of the nature of a suit which a Missouri woman is said to have once brought against a railroad. The Missouri woman was a passenger on the railroad and, having been accidentally carried beyond her destination some distance, the train stopped and she alighted. While returning she was chased by a bull, and her suit was based upon the claim that in outrunning the bull she impaired her health.

Fourth International Gynecological and Obstetrical Congress.—It is announced that this Congress will be held in Rome about September 15, 1902. The following names appear in the Italian Committee on Organization: Pasquali, President General; Mangiagolli and Morisani, Presidents; Pestalozzi, Secretary General; La Torre, Treasurer; Caruso and Regnoli, Secretaries; Truzzi, Calderini, Guzzoni, and Negri, Counselors.

Prof. Behring's Work.—News is received that Prof. Behring, at a Conference on Serumtherapy, reported successful results in his endeavors to render animals immune to tuberculosis through serum injections. The Noble prize awarded to him will be used for the pursuance of further research in the prevention of bovine tuberculosis.

Depopulation?—Statistics show a decrease in the birth-rate in Prussia of 5 per cent., England 10 per cent., France 14 per cent., and Belgium 15 per cent.

A Versatile Physician.—The following is an advertisement published in Shakespeare's time: "Wanted —for a family of invalids, a reliable and faithful man who is a competent physician, surgeon, and obstetrist; he must also take charge of the wine cellar and table service, and understand the carding of hemp, and construction of wigs. Every Sunday he will be expected to deliver a sermon, and, if necessary, conduct religious services. A liberal salary will be paid."

Smallpox in Hackettstown.—The smallpox situation is unchanged in this place. There are now forty-five cases reported. No new cases have occurred.

Sells M.D. Diplomas.—The Postmaster-General issued an order January 10th denying the use of the mails to the "Central University of Medicine and Science," and J. W. Norton Smith, President, 68 Montgomery Street, Jersey City. The university represented that it was an incorporated institution in good standing and that it had an extensive medical faculty. To those desiring to practise medicine the University of Medicine and Science sold diplomas at prices ranging from $5 to $20, according to the ability of the prospective M.D. to pay. The scheme is identical with that operated in Chicago by James Armstrong, under the title of the Metropolitan Medical College. Armstrong was tried before Judge Kohlsaat in the United States Circuit and sentenced to one year in jail. The Department of Justice will probably take action against J. W. Norton Smith, who is named in the fraud order as the promoter of the present scheme.

New Sydenham Society Publication.—Jonathan Hutchinson, F.R.S., General Secretary of the New Sydenham Society, has requested Messrs. P. Blakiston's Son & Co., of Philadelphia, the American agents of the Society, to announce the publication of "An Atlas of Clinical Medicine, Surgery and Pathology," selected and arranged with the design to afford, in as complete a manner as possible, aids to diagnosis in all departments of practice. It is proposed to complete the work in five years, in fasciculi form, eight to ten plates issued every three months in connection with the regular publications of the Society. The New Sydenham Society was established in 1858, with the object of publishing essays, monographs and translations of works which could not be otherwise issued. The list of publications numbers upward of 170 volumes of the greatest scientific value. An effort is now being made to increase the membership, in order to extend its work.

Obituary.—Dr. Joseph S. Carreau, who has been an active physician in New York City for the past thirty-eight years, died recently at his home in that city of heart disease. Dr. Carreau was born in Canada, and his work was principally among the French Canadians in New York. He was a graduate of Bellevue Medical College and a member of the New York County Medical Society.

Dr. Grove H. Wilson, former mayor of Meriden, Conn., died last week from enlargement of the heart. He was seventy-eight years old.

Dr. George Covert died at Clinton, Wis., last week, as a result of a cold. He was seventy-three years old, and had been president for several successive terms of both the National and the State Eclectic Medical associations.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, January 4, 1902.

THE KING AND THE CRUSADE AGAINST CONSUMPTION—A MAGNIFICENT DONATION FOR A ROYAL SANATORIUM—THE GIFT AND THE GIVER—THE INNER HISTORY OF THE AFFAIR—PRIZES OFFERED FOR INTERNATIONAL COMPETITION.

VESPASIAN, who, as historians tell us, died on a close stool, cynically described the situation in his last words, *Ut puto, deus fio.* We laugh at the Romans for deifying their emperors, but have we, the subjects of His Gracious Majesty Edward the Seventh, King of all the Britains and Emperor of India, any right to laugh at them? The Romans waited till their sovereigns were dead before they made gods of them; but we come very near to deification of ours while they are still alive. It is a fundamental principle of the British constitution that "the King can do no wrong;" but his lieges have stretched this principle into a dogma that whatever the King does must necessarily be, in the words of our most uninspired national anthem, "gracious and glorious." Hence the announcement made this week that King Edward is about to found a sanatorium for consumptives has been hailed by the newspapers with a chorus of adulation which recalls the groveling dedications of books to royal patrons of a bygone day. His Majesty's solicitude for the well-being of his people; his intelligent interest in medical science; the enthusiasm with which he has thrown himself into the crusade against consumption, are celebrated with a wealth of laudatory epithets and a tropical luxuriance of verbiage that would be exaggerated if applied to the active benevolence of a Titus or the constructive statesmanship of a Napoleon. If the King himself had given the money for the building and endowment of the sanatorium, the act would justify some part at least of the pæans that have been sung in his praise. But his share in the matter is simply that he acts as the almoner of one of his subjects who has placed a sum of one million dollars in his hands to be used for utilitarian or charitable purposes. This seems easy enough, but in reality it is a great deal in a country where royalty is worshipped with far greater devotion than is paid to the Almighty. The gold of the philanthropic millionaire is but common metal till it is touched by the royal fingers, when it becomes transmuted into something sacred and acquires thaumaturgic properties, in particular a singular power of attraction which ensures the success of the object for which it is given. The King's sanatorium is sure to be successful simply because His Majesty has deigned to allow his name to be associated therewith.

The history of the gift is interesting as affording a glimpse into the inwardness of our British life, which outwardly looks so stolidly respectable. The money has been given by Sir Ernest Cassel, a multimillionaire who has financed the Egyptian Government, and also, it is whispered, Edwardus Rex himself. The said Cassel is, like the late Baron Hirsch and other financial supporters of His Majesty, a Hebrew; his immediate origin, however, is not from Judea, but from Germany, his father having been something in the money-broking way at Cologne. Besides his vast pile of ducats Cassel, like his compatriot Shylock, has a daughter. The young lady fell ill not long ago, but fortunately physicians were not in vain. It would have been passing strange if they had, for they were Sir William Broadbent and Sir Felix Semon. Whether it was gratitude to either or both of these oracles of medicine, or the glitter of a prospective coronet at the "Coronation Honors," that moved the financier to lay his million of dollars at the royal feet, deponent knoweth not. But there is already a good deal of heart-burning on the subject, and there is going to be more. The money, it is said, was at first intended for the National Association for the Prevention of Consumption in which the King has from its foundation taken a keen interest, as he showed on the occasion of the Tuberculosis Congress held here under its auspices last summer. In some mysterious way, however, the donor was induced to offer his shekels directly to the King. Hence there is much gnashing of teeth among the leading spirits of the Association. It may be nothing more than a coincidence that Sir Felix Semon, who, like Sir Ernest Cassel, is a German Jew and is supposed to nourish a grievance against the organizers of the Congress for some alleged failure to recognize his high position in the medical hierarchy, has taken a prominent part in the matter. It is a fact, however, that the Advisory Committee chosen by the King to carry out the scheme consists, with one or two exceptions, of men who are known to be hostile to the movement against tuberculosis initiated by the National Association. The King is probably not aware of the use that is being made of him to gratify personal jealousies and avenge real or supposed injuries. But he will learn it before long and then there will be trouble. It is not surprising, therefore, that one of the most prominent members of the Advisory Committee is already anxious to be out of the business. And there is more behind.

When the rumors about the King's health were flying about, some of the Continental papers stated that a Dr. Besold, a German laryngologist, had been called to see His Majesty. It turns out that Dr. Besold, whose name is unknown to the medical profession of this country, is assistant medical superintendent of the sanatorium at Falkenstein. The King visited that place some years ago and was, as he stated publicly afterward, greatly impressed by what he saw. He visited it again a few months ago in company with one of his physicians, Sir Francis Laking, and doubtless on one or other or both of these occasions he made the acquaintance of Dr. Besold. Then an English "lady of quality" came on the scene. She was sent to Falkenstein and seems to have been fascinated by the German physician, whom she brought over to England to see the King, not to give counsel about the royal throat, but to discuss the matter of a sanatorium. It is said that it is the King's intention to appoint Dr. Besold head of the new foundation. Here again King Edward is being made use of to push the private ends of some intriguing individuals. The Advisory Committee which has been appointed consists of Sir William Broadbent, Sir R. Douglas Powell, Sir Francis Laking, Sir Felix Semon, Sir Hermann Weber and Dr. Theodore Williams. There are, therefore, two Germans on the Committee; if a German physician is placed at the head of the sanatorium, much dissatisfaction will certainly, and I think justly, be felt by the medical profession of Great Britain. Already the royal family largely patronizes German practitioners of one kind or another and recommends them to their friends. Such a recommendation is in this snobocratic country equivalent to a command; hence, native talent is ignored that the horn of the Germans may be exalted. On the whole the omens seem to point to a tremendous outbreak of squabbles and scandals as the result of what is ostensibly an act of pure philanthropy. It may turn out that the German financier has thrown a veritable apple of discord among the King and his medical counselors.

I should say that it will be a year or eighteen months before the scheme finds actual embodiment in bricks

and mortar. The Advisory Committee offer $4,000 in prizes for the best essays and plans for a model sanatorium and the competition is open to medical men of all nationalities. As the precise conditions of the competition may interest some of your readers, I give them in full:

1. Medical men of all nationalities may compete. The papers may either be the work of a medical man, or the joint production of a medical man and an architect.

2. The sanatorium is intended for 100 tuberculous patients, 50 male and 50 female.

3. Of the total number of beds, 88 will be assigned to the more necessitous classes, whilst 12 will be reserved for the well-to-do.

4. The accommodation for all patients is to be comfortable, a separate room being provided for each. Superior arrangements are to be made for the more wealthy patients.

5. It may be taken for granted that the sanatorium will be erected on an elevated and sloping site with a sunny exposure, and well sheltered from cold winds. It will have a farm at a convenient distance and be surrounded by extensive grounds, well wooded, and affording ample space for exercises of various kinds. The soil will be dry and permeable, and the water supply will be abundant.

6. The sanatorium must be fitted with all the latest sanitary arrangements and equipped with all requirements for scientific research. Provision should also be made for the recreation of the patients.

Economy in construction will be an important consideration, but it must not interfere with the reasonable comfort of the patients or the efficiency of the institution.

8. The essays must be in English and typewritten.

9. The essays must not bear the name or names of their authors, but should have a motto and each essay should be accompanied by a sealed envelope bearing the motto on the outside and containing the full name and address of the author or authors inside.

10. Three money prizes of £500, £200, and £100 respectively, will be awarded in order of merit on the recommendation of the Advisory Committee for the three best essays, provided they come up to the requisite standard of excellence. Brevity will be an important consideration, and a summary of the main features of the scheme should be appended to the paper. Unsuccessful papers will be returned to the author.

11. All essays and plans must be sent, postage paid, on or before April 15, 1902, to one of the Secretaries of the Committee: Dr. P. Horton Smith, 15 Upper Brook Street, London, W., or Dr. John Broadbent, 35 Seymour Street, London, W.

LUCAS-CHAMPIONNIÈRE, at the Academy of Medicine, December 3, 1901, continued the discussion of Jacksonian epilepsy with reference to cerebral localization. Tumors of the brain show symptoms which vary greatly and make it difficult to determine the time and point of surgical attack. As to the time of surgical intervention he disagreed with Raymond, who at the preceding meeting said that he thought that operation could usually be delayed until paralysis was definitely established. Lucas-Championnière claimed that a partial epilepsy and very acute symptoms justified an operation with the hope of removing the cause before it was too late and paralysis had become fixed. Jacksonian epilepsy itself may not always justify operation, but as a rule it furnishes indications for operation for the troubles which accompany epilepsy in the majority of cases.

ROBIN read in behalf of Binet, Dupasquier and himself the experiences which Dupasquier had undergone while making balloon ascensions. The most important facts noted were an increase in the number of pulsations of the heart and of respirations, whose frequency increased proportionately with the altitude, and a diminution in the capacity of the lungs which seemed to be in inverse ratio to the altitude. Furthermore, the gas excreted by the lungs decreased in the amount of carbonic oxide gas without direct reference to the altitude; as to the ventilation of the lungs he found an irregular progress compared with the altitude. The respiratory changes were also increased according to the quantity of oxygen absorbed by the tissues. These various modifications did not cease immediately upon return to earth. The author added that possibly many of these factors depend upon others, namely, the degree of cold and the age of the subject. Herein he disagrees with the observations of other authorities, Tissot and Hallion, who claim that the individual is sufficiently dominant for generalizing the whole results. It therefore appears that definite conclusions on this point cannot yet be arrived at.

ROOS, at the Academy of Sciences, November 25, 1901, stated that before concluding his researches into the question of the influence of wine upon healthy subjects he proceeded to verify by experiments the usual opinion to the effect that tuberculosis develops more rapidly in individuals who drink alcohol, especially if this is in the form of fermented liquors. For the purpose of proof he inoculated with tuberculosis six pairs of young guinea-pigs. Of these three were subjected to an ordinary diet, while the other three received during about one month and were still continuing to receive 35 cubic centimeters of wine a day for each kilogram of weight. At first the animals of the second group lost in weight considerably more than those of the first. None were adult animals and all continued to develop well. At the end of fifty days the weight curves of both lots of animals became parallel and almost the same. Later peculiar variations in weight appeared, first of the alcoholic and then of the non-alcoholic series of animals, first the one weighing more and then the other. Finally, the inoculation was done on the ninety-fourth day on the alcoholic animals and on the ninety-fifth day on the others; one guinea-pig of the first group was the last to die. His conclusion from his observations is that alcohol even in large doses does not have much influence on the experimental development of tuberculosis in the guinea-pig.

WALTHER, at the Surgical Society, November 27, 1901, reviewed the clinical facts concerning a case of penetrating wound of the spinal canal with complete division of the spinal cord. He operated on a woman last year for such a wound in the dorsal region caused by a revolver shot. The patient presented a paralysis complete in both lower extremities with the abolition of both reflexes, although right after the injury she was able to get up and take one or two steps, consequently the diagnosis was compression of the spinal cord by hemorrhages. Therefore on the fifth day, owing to the appearance of trophic troubles in the form of chipping of the nails and other trophic signs in the sacral region, it was decided to interfere. There was

also at the same time a penetrating wound of the chest which had caused a hemopneumothorax which had slowly begun to disappear owing to the trophic symptoms already enumerated. The diagnosis was changed to one of probable division of the spinal cord. Stereoscopic radiography showed that the bullet was situated in the spinal canal just beneath the right root of the vertebral arch in the second dorsal vertebra. Here the bullet was found at the operation without meeting anything but a little hemorrhage. The spinal cord was unfortunately cut entirely across and there was a space of half an inch between the two stumps. Nothing whatever could be done. The unfortunate woman died two and one-half months after the injury.

Fontan stated that he had had a successful case of suture of the heart for stab wound. The operation was done two hours after the injury and is the second of the kind which he has performed. He made a flap in the front of the chest, taking in the fourth, fifth and sixth costal cartilages beneath which he found a wound of the pericardium. This he enlarged enough to get a fair view of the heart which presented a cut in the ventricle about 15 mm. above the apex. This he proceded to suture with a Hagedorn needle and a medium-sized catgut. Complete arrest of the hemorrhage was obtained fifteen minutes after the operation. During the operation about one liter of salt solution was injected. After a period of disquiet the injured man began to pick up in a very satisfactory manner. Later, however, trouble in the lung began at the base, owing, perhaps, to a small embolus; on the sixth day symptoms of infection also developed on the left side in the chest and made it necessary to do a thoracotomy. Finally a phlebitis of the lower limb on the right side added still more to his complications. Nevertheless, the patient recovered.

Lancher, at the Medical Society of the Hospitals, reported in his name and in that of Lacapère an observation of a man, sixty years old, who during the course of a severe jaundice was overtaken by a right-sided hemiplegia involving the face and accompanied by hemichorea, hemi-anesthesia and contracture. Although the man denied ever having had syphillis, the presence on his tongue of two small areas of fibrous leucoplasia made the observers think that syphilis was at the bottom of the hemiplegia. They afterward gave him every day an injection of benzoate of mercury and prescribed iodide of potash. Four days afterward the paralysis had almost completely disappeared and there were left only a few choreiform movements and light exaggeration of the reflexes at the knee and a little hypo-esthesia on the right side. According to the author such spots within the mouth are always of syphilitic origin. Usually treatment with mercury is not effectual against them.

Bardier presented three cases of bradycardia, which he has observed in children recovering from diphtheria. In one case the pulse fell to 62; in another it remained for about fifteen days at 60. In none of the little patients in question was this phenomenon of the heart accompanied by signs of functional trouble. The only way of perceiving the condition was by a methodical daily examination of the pulse. All three left the hospital apparently cured. Although bradycardia is an abnormal phenomenon and an exception in the course of diphtheria, it possesses no great gravity, although many authors have stated that it always precedes a fatal issue.

Gaucher gives the following formula for an isotonic artificial serum for dissolving benzoate of mercury: Chloride of sodium, gram 0.75; benzoate of mercury, gram 1; sterilized water, grams 100. The injection must be made deeply into the cellular tissue in the buttock and not into the muscles. The dose may be 2 cubic centimeters and it is very well borne even without cocaine and occasions only a little pain; sometimes there is absolutely no pain.

Sicard, at the Society of Biology, November 30, 1901, read a paper on the chromo-diagnosis of the cephalorachidian fluid in cases of hemorrhage into the nervous system. During such hemorrhage, whether in the brain or the spinal cord, the cephalorachidian fluid withdrawn by lumbar puncture presents at times a yellowish or a greenish-yellow discoloration caused by a solution within it of the blood elements. In most of the cases there was not true hemoglobin present, but a special chromogen which had no influence on the solar spectrum at the level of the line made by hemoglobin and did not give the reaction by indirect oxidation by the tincture of guaiac and oxidized water. This special discoloration of the fluid may appear on the third day and remain perhaps for about eighteen days. Up to the present time no similar condition of the fluid has been found, excepting in severe cases of jaundice; therefore, with the exception of jaundice, the positive chromo-diagnosis constitutes a certain proof of hemorrhage somewhere within the nervous system or its immediate covering. If negative, of course, it does not disprove the presence of a hemorrhage. It is only when the fluid possesses this yellowish color and not a real blood color that one may think of an old hemorrhage.

Roy, at the Medical Society of the Hospitals, November 6, 1901, presented in the name of Variot a four-year-old child in which they had found the three chief symptoms of exophthalmic goiter, namely, the goiter, the exophthalmos and the tachycardia. The child was at once given thyroid extract; the pulse fell from 160 to 140, the anemia disappeared and there was an increase in weight of 3.50 kilograms. This seems to be the only published case of this disease in so young a subject.

Rathery and Chauffard exhibited the brain of a man who died a few days previous of apoplexy which followed a right hemiparesis with motor aphasia. The lesion was situated exactly at the base of the third convolution in the left frontal region. It consisted in a red softening due to the plugging up of the Sylvian artery. It was limited strictly to the cortical substance, which was proven by making numerous sections of the brain beneath this region.

Levi and Lemierre discussed the case of a man twenty-four years old who, during the course of a mild typhoid fever, showed symptoms of cystitis. A bacteriological examination showed in the urine numerous bacilli of Eberth, which continued to be present three months after the appearance of the cystitis. The fact that the urine of a typhoid-fever patient can contain this bacilli with or without the signs of cystitis is interesting in the point of view of prophylaxis of the disease. It makes it necessary, therefore, to destroy the urine of such patients as well as their feces in order to prevent the spread of their disease.

Mosse presented a contribution in which he reported a certain number of new observations tending to prove that, in the treatment of various kinds of diabetes and their complications, potatoes may with advantage be substituted entirely for bread. It must be remembered, however, that such treatment is equivalent to the alkaline treatment on account of the large quantity of potassium contained in this element. The best patients for whom to prescribe this class of diet is such as do not suffer from chronic nephritis, because potassium increases the toxicity of the blood.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 19, 1901.

The Vice-President, Hermann Knapp, M.D., in the Chair.

THE scientific proceedings of the evening consisted of a discussion on tuberculosis and the prevention of tuberculosis, with an introduction by Dr. E. G. Janeway. Dr. Janeway's remarks were founded on the papers read and their discussion at the British Congress on Tuberculosis last August, at which he was in attendance as a delegate from the United States. Dr. Janeway's report will appear in a subsequent issue of the MEDICAL NEWS.

The first paper in the discussion of Dr. Janeway's report was read by Dr. Theobald Smith. Its subject was "The Difference Between Bovine and Human Tuberculosis." This paper will also appear in a subsequent issue of the MEDICAL NEWS.

Danger from Bovine Tuberculosis.—Dr. Hermann M. Biggs in discussing Dr. Smith's paper said that Koch's declaration has made the subject of human and bovine tuberculosis and their relation to each other and to disease in man of intense present-day interest. Koch's position as announced at the Congress involves two considerations—first, he claims that bovine and human tuberculosis and the bacilli which cause them are different, which position is not proven, and, secondly, that the danger of infection of human beings by bovine tuberculosis may be ignored. There is no doubt that the main factor in the distribution of tuberculosis among human beings is human tuberculosis in those living near them. Health authorities realize how significant human contagion is because of the immense amount of tuberculosis which exists in tenement-house districts. As high as eighteen to twenty per cent. of the deaths among the population in certain parts of the city that are especially crowded are due to tuberculosis. In other parts of the city, where there are ample living space, light and air, the mortality is less than one-quarter of one per cent. The English statistics with regard to the origin of tuberculosis in human beings are very different from our own and also differ very strikingly from the Continental statistics. Sir Thorne Thorne, some two years ago in his lectures on the dangers of the spread of tuberculosis, collected statistics to show that ten per cent. of the deaths from tuberculosis in England take place from tabes mesenterica. He argues from this that the main source of infection is milk, though probably also meat infected with bovine tuberculosis has something to do with the spread of tuberculous disease, especially of the intestines. He pointed out, also, that while the general death-rate from tuberculosis was decreasing, the death-rate from the abdominal form of tuberculosis was on the increase.

American Statistics.—Our statistics differ very materially from those of England in this matter. Death from primary intestinal tuberculosis is very infrequent in this country and especially in this city, where proper examinations are made in order to determine the origin of the tuberculosis. The death-rate from tabes mesenterica is less than one per cent. Our statistics agree in this matter with those of Germany and of France. There is evidently some factor entering into the English statistics that makes them inapplicable to conditions in other countries. Our statistics for primary intestinal tuberculosis confirms Koch's position that the danger from bovine tubercle bacilli taken into the human system is so small that it can be practically ignored.

Limitation of Animal Tuberculosis.—The question of the limitation of tuberculosis in animals is then not a human, sanitary problem, but an agricultural problem. The prevention of bovine tuberculosis is of extreme economic importance, but it must not be urged upon the community on the ground of danger to human beings because of the possibility of infection.

Experiments Upon Human Beings.—The inoculation of human beings with bovine tuberculosis is out of the question. Certain experiments in this line have been done in the past however. Baumgarten reports that Rokitansky inoculated with tuberculous material certain persons, ten or twelve in number, who were suffering from cancer and were considered to be hopelessly ill. It had been observed that cancer patients did not suffer from tuberculosis, nor tuberculous patients from cancer. It was thought possible that the one disease might have some influence upon the other. Hence, the experiments were not entirely unjustified even from a humanitarian standpoint, as there seemed some faint hope of therapeutic benefit. The cancer patients were inoculated subcutaneously. Some local reaction took place, but no general infection occurred. At the autopsy no trace of tuberculosis could be found anywhere in the internal organs.

Human Susceptibility.—Dr. William H. Park said that, while it cannot be predicated of any specific animal infection that it will infect any other kind of animal, it is well known that when an infectious material proves pathogenic for a number of classes of animals very few animals are immune to it. Infections that are virulent for many animals are usually pathogenic also for man. There are many anomalies, however, in susceptibility. Rabies affects monkeys, but after it has passed through a series of monkeys the infectious material loses its virulence for dogs. On the other hand, rabbits are extremely susceptible to rabies, but any number of passages of the virus through rabbits does not diminish its virulence for dogs. Tuberculosis is a most insidious disease. It is practically impossible to tell the exact time of its origin in any given case. Hence, the difficulty of determining what is the exact cause of a tuberculous process in any given individual. In order to determine whether human tubercle bacilli would affect cattle, Dr. Park has had four suckling calves fed on sputum from tuberculous patients. Among them was distributed all the sputum collected daily from the tuberculous patients under treatment at St. Luke's Hospital. After three months the animals gave a reaction to tuberculin, though there was no reaction just after birth. When killed, however, no trace of tuberculosis could be found in their tissues. It is possible that more careful search might have shown a very limited area of tuberculosis somewhere in the tissues as the result of the presence of which the tuberculin test became positive. In this series of experiments there seemed very good reason to think that the animals should suffer from the disease if they were at all susceptible. They were kept in a rather cold, dark room and were evidently not up to the usual standard of health as a consequence. Some human tubercle bacilli were also subcutaneously injected. These produced local abscesses, but no generalization of the infection. It would seem clear then that human tubercle bacilli do not infect cattle when ingested or injected under ordinary conditions.

Danger of Bovine Tuberculosis.—It is well recognized now by bacteriologists that for susceptible animals bovine tuberculosis is much more virulent than human tuberculosis. It is possible that even, though human tuberculosis does not affect cattle, bovine tuberculosis may prove serious for human beings. This

would be especially true in young and delicate subjects and if, as is so often the case in infants, because of lack of variety in the diet, a considerable number of tubercle bacilli found their way into the intestines at one time the danger might be very great. It seems clear, therefore, that we must not lessen our precautions, though the question of the interchangeableness of human and bovine tuberculosis still remains open for discussion and is an extremely valuable field for study.

Human Tuberculosis from Cow's Milk.—Dr. Abraham Jacobi quoted a number of articles that have recently appeared in English and German medical journals with regard to the question of the possible origination of tuberculosis in human beings from cow's milk. Practically all writers are agreed that certain cases of human tuberculosis are etiologically connected with tuberculous cow's milk. There are many series of cases in infants reported in which this connection seems beyond doubt. This does not prove that the tuberculosis in infants originates frequently from cow's milk, but it does demonstrate that there is a certain amount of danger. Dr. Jacobi himself has reported a case of ascites in which tubercle bacilli were demonstrated, though no tuberculous lesions could be found in any other part of the body. Other such cases have also been reported. It is probable that in these cases the only explanation that can be accepted is that tubercle bacilli have come from the intestines. This does not necessarily infer that there are visible lesions of tuberculosis in the intestines. Tubercle bacilli and other micro-organisms may penetrate what to all intents and purposes so far as ordinary examination is concerned, is an unbroken mucous membrane. In Dr. Jacobi's case no tubercle bacilli could be found in the blood and there were no signs of miliary tuberculosis or of pulmonary tuberculosis, so that the bacilli surely came from the intestines. The intestine of young children is particularly predisposed to let bacilli pass. Hence, the frequency with which primary tuberculosis of the peritoneum occurs. As a matter of fact, peritoneal tuberculosis is nearly always isolated and tubercle bacilli are often able to find their way into the free abdominal cavity. In peritoneal tuberculosis the mesenteric glands are not always, nor necessarily, enlarged. In a word, tubercle bacilli succeed in finding their way to the peritoneal surface without the production of visible lesions along the paths through which they have come from the intestine. Dr. Jacobi believes that the danger of contracting tuberculosis through the intestine is underestimated and is liable to be more so, because of Koch's declaration and its effect upon the public mind. Intestinal tuberculosis is rare, but even these rare cases should be prevented. Generalized tuberculosis when the peritoneum is also involved usually originates in the peritoneal cavity. The infection practically always comes from the intestine. No matter how few the cases, then, it would be difficult to overestimate the danger of intestinal tuberculosis.

Not Agricultural but Hygienic Problem.—Dr. Jacobi thinks therefore that we can not have laws too strict for the regulation of the milk supply, so as to avoid the danger from tuberculous milk that certainly exists. The care of the dairy and the guardianship of bovine tuberculosis is not an agricultural, but a great hygienic problem. Time and money devoted to it are not in the interest of the farmers of the country and the dairymen, but of the human population and its health and especially the health of its infantile members.

Rarity of Intestinal Tuberculosis.—Dr. W. H. Northrup said that he has never seen a case where clinically he believed in the existence of a primary mesenteric tuberculosis. He has made autopsies on 125 cases of infants who had died from tuberculosis under the care of the New York Foundling Asylum. These children had been distributed among families who would care for them and were, as a rule, fed on grocery milk. Every opportunity was presented then for the contraction of intestinal tuberculosis, but in only three cases did there seem to be primary intestinal tuberculosis. In 34 cases of general tuberculosis there was also peritoneal tuberculosis. In 13 cases the only parts affected were the bronchial lymph-nodes. Dr. Northrup said that in his experience peritoneal tuberculosis was not always, nor even usually, due to primary infection. On the contrary, as a rule the infection of the peritoneum seems to come after many other organs and tissues have been infected. In most cases, then, tuberculosis of the peritoneum appears to be the result of overflow of the tubercle bacilli from the system at a time when they exist so freely in the body that generalized infections have become possible.

Minimal Danger from Bovine Tuberculosis.—Dr. David Bovaird confirmed Dr. Northrup's statistics by a like series of his own in which only two cases of primary intestinal tuberculosis were noted. Recently Drs. Pearson and Ravenel in the Pennsylvania State Reports announced that in fifteen herds they found eighty per cent. of the cattle tuberculous. The milk from these herds had been very generally used in the neighborhood for the feeding of children. There was, however, no special incidence of intestinal tuberculosis in the vicinity thus supplied with milk nor any notable increase of the usual mortality from tuberculosis among infants. If there was much danger from the taking of tuberculous milk there should surely be convincing proof of it at hand by this time. As there is no absolute evidence, it would seem that there is but little danger from milk.

NORTH BRANCH OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Held December 20, 1901.

H. Booker Mills, M.D., in the Chair.

The Differential Diagnosis of Variola, Varioloid and Vericella.—Jay F. Schamberg read this paper. He first called attention to the liability of error in the diagnosis of smallpox, which he classified under two heads, (1) the overlooking of the true nature of the disease and diagnosing it as something else, and (2) the mistaking of some other disease, such as chickenpox or measles, for smallpox. The period of incubation in smallpox is about twelve days, the pyrexia begins at this time and the eruption usually appears about a couple of days later. During the latter days of the period of incubation the patient usually suffers from malaise, general lassitude, loss of appetite and chilliness. These symptoms vary in intensity and are sometimes very marked toward the end of the second week of incubation. Smallpox usually begins with a chill of varying severity and is often associated with headache and frequently with backache. Attention was called to the fact that too much stress should not be placed on the latter symptom, as various other causes may produce it, and this is one of the most common errors. Among other symptoms sometimes present may be mentioned vomiting, fever, prostration, pain in the pit of the stomach, nausea without vomiting, vertigo, especially in the mild cases, and general soreness, both muscular and cutaneous, the latter symptom often causing the mistake of diagnosing a case of influenza as smallpox. The patient's temperature may rise as

high as 105° F. and may be accompanied by delirium, coma or convulsions, the two latter symptoms being more frequent in children. Sometimes the patient does not experience any initial symptoms. In 100 cases which recently came under the author's observation he found that headache was present in 86 cases; chills in 78; backache in 70; vomiting in 58; nausea without vomiting in 10. In only 2 of these cases were initial symptoms absent, although the cases included all forms of smallpox from the mildest to the most severe. The vaccine roseola which occurs eight or ten days after vaccination resembles very much the rubeola rash. Chicken-pox, which is probably more often mistaken for smallpox than any other disease, has the following distinguishing features: The eruption occurs chiefly on the covered surfaces, particularly the back. The papilla may vary in size, and some often appear several days after the first have been observed, while eruption in smallpox occurs chiefly on the exposed surfaces of the body, is of uniform size and comes out almost all at one time. The character of the lesions in the two diseases is also very different, the smallpox lesion being a firm, shotty papilla developing into a vesicle. Another important factor in the differential diagnosis of these diseases is whether or not the patient has been recently vaccinated, for, if a good vaccination scar is present, one can more safely exclude the possibility of smallpox. One of the most difficult diseases to distinguish from smallpox is pustule syphiderm, and many instances are recorded where one has been mistaken for the other, the most important feature in the differentiation being the previous clinical history of the patient.

Vaccine Virus, Its Preparation and the Accidents Following Its Use.—This was the title of a paper read by Dr. Joseph McFarland. Reference was made to the early history of vaccinia or cowpox and attention directed to the fact that the exact relationship which this disease bears to smallpox has never been clearly ascertained, although it has been observed that it was most prevalent among cattle when smallpox was at its worst among the human race. The characteristic features of vaccinia are marked constitutional symptoms and a rash limited to certain parts of the cow's body. The author referred to the difficulty that has always been experienced in transmitting any disease from man to cattle and cited in support of this theory the fact that, although syphilis and gonorrhea are everywhere recognized to be produced by micro-organisms, yet it is impossible to transmit these diseases to the lower animals. This difficulty in the transmission of disease from man to the lower animals, he thinks is due to the difference in the soil in which the germ is implanted and the difference between variola or smallpox in man and vaccinia or cowpox can no doubt also be explained on this basis, as but few of the attempts to transmit human smallpox to cattle by inoculation have proven successful. Reference was made to inoculation as the method in use for the protection of man from smallpox prior to the introduction of vaccination by Jenner, and the drawbacks of this mode of immunization were commented upon, prominent among them being the facts that the operation must always be performed when the patient was in the very best of health and even then a condition very similar to a slight attack of the disease itself was frequently experienced. The various advances in vaccination from the introduction of the original method up to the present time were noted and the advantages and disadvantages of vaccination with bovine virus over vaccination with human virus were discussed. Prominent among the former is the rarity of the occasions in which any micro-organism from the lower animals will develop in the human system, the chief objections being the liablity of the transmission of tuberculosis, which, however, the author considered as of but little import, owing to the fact that extreme care is used in the selection of the animals for this purpose and, as is sometimes claimed, the immunity following vaccination with human virus is considerably longer.

Classes of Micro-Organisms Found.—In the opinion of the author it is impossible to eliminate the micro-organisms from the virus; he considers that there are three kinds which are always present, namely, (1) the unknown specific micro-organism of vaccinia, (2) the micro-organisms from the skins of the animals, and (3) the micro-organisms that get into the virus accidentally from the air, instruments, hands, etc., during its preparation. By the use of glycerin in the preparation of the glycerinized virus no doubt many of the micro-organisms of the two latter classes are destroyed, as they seem to be more susceptible to this germicidal agent than the micro-organisms of vaccinia. Owing to this fact the author feels that the glycerinized virus is to be preferred to the dry points which are also used to a considerable extent by many physicians.

Study of Vaccination Scars.—Dr. William Welch read a paper entitled Deductions from Studies of Recent Vaccinations; Interpretation of Old Scars; Complications of Vaccination. In order to give some idea of the value of vaccination the author commented upon the fact that of the eight hundred people admitted to the Municipal Hospital in Philadelphia during the present epidemic of smallpox not a single case had recently been successfully vaccinated. Numerous instances have been observed where whole families have been taken to the Hospital, one of them suffering from this disease, and, although they had all been continuously exposed to smallpox for several weeks, those members who had recently been successfully vaccinated remained entirely immune. Instances have also come under his observation where vaccinated infants have taken their daily nourishment from the breast of their mother suffering from varioloid and have remained entirely free from smallpox. A number of similar instances were cited and attention was directed to the fact that where the proper precautionary measures of vaccination prior to taking up their duty in the smallpox wards has been observed, the author in his thirty years' connection with this Hospital has never seen a resident physician or nurse contract the disease.

The Technic, Value and Object of Vaccination.—This was the title of a paper read by Dr. Judson Daland, in which he emphasized the importance of proper cleansing of the skin prior to the operation. If the patient be a female he advises that it be done upon the antero-external aspect of the lower fifth of the thigh, and in a male it should be performed upon the antero-internal portion of the middle third of the left arm, provided he is right-handed. Not only should the skin be thoroughly cleansed, but it should be rendered aseptic by the free application of alcohol followed by ether. The author recommends the use of a sterilized steel five-pointed scarificator, which should be drawn parallel with tne long axis of the limb and the scratching continued until there appears over a surface about a quarter of an inch in diameter a moisture composed of serum slightly blood-tinged, after which the scarificator should be moved at right angles until the wound presents a uniform pink appearance due to slight exudate of blood-stained serum. After this the virus should be applied and brought into thorough contact with the abraided surface by means of the scarificator, and an ordinary shield applied which the patient should be instructed to remove in twelve hours, when under ordinary circumstances a sufficient scab will have

formed to prevent re-infection of the wound from the skin or outside. The wound should be further protected by a simple surgical dressing, which should be removed, the wound cleansed and a fresh dressing applied nightly. As soon as the first evidence of inflammation shows itself, the physician should carefully cleanse the point of vaccination and surrounding skin with abundance of sterile hot water and white Castile soap, and, after thorough drying with alcohol, care being taken not to disturb the scab, the surrounding skin should be rubbed with simple oxide of zinc ointment, or, better still, with an ointment composed of five grains of boric acid to the dram of lanolin and almond oil. A surgical dressing composed of a thin piece of lint covered with this ointment should be placed over the pustule, over which should be placed a thin layer of borated absorbent cotton, the whole being held in place by a rubber bandage. This local treatment should be repeated once, twice or thrice daily, depending upon the amount of suppuration. Attention was directed to the value of vaccination as an immunizing agent and various statistics tending to prove this were quoted, notable among which were the observations made by Dr. Koch during an epidemic of the disease in Germany, which showed the mortality-rate among the unvaccinated to be 32 per cent. while among those who had availed themselves of this protection it was only 9.5 per cent.

Tetanus Following Vaccination.—Dr. William L. Kelchner of Camden, N. J., read a paper in which he gave a full account of this condition in cases which had recently come under his observation. There was but a very short period of incubation, and the author inclined to look upon the virus used as the source of the infection. Tetanus antitoxin was administered in the early stages of the disease, and it is to the prompt employment of this remedy that the author attributes the recovery of the patients. Strychnine was also given hypodermically in large doses. In his opinion the antitoxin to be of value must be administered promptly. The author feels that with care in the preparation of the patient, as outlined by Dr. Daland, tetanus would be avoided.

Dr. William F. Elgin, who has had large experience in the preparation of vaccine virus, opened the discussion and his remarks were particularly directed toward this subject. He commented on the fact that because a person will take vaccination it does not always follow that they will take smallpox, if exposed to the disease, citing in support of this theory that he has had under his observation for the past two years from two to three hundred young people employed in the manufacture of virus and has observed that when any one who has not been successfully vaccinated since childhood comes to work in the laboratory they immediately vaccinate themselves in any abrasion that may occur on the fingers, on the hands or even on the face, which is frequently followed by a revaccination in the same manner two or three weeks later, and he has observed instances where the same person would within twelve months vaccinate themselves in the same manner for the third time. In order to secure protection against vaccination he believes that it is necessary to vaccinate to the point of saturation, which he thinks is rarely reached by the methods practised in this country. Regarding the comparative values of human virus and bovine virus for vaccination, he remarked the fact that Mexico, where the use of human virus predominates and where it is claimed that the immunity lasts from thirty to forty years, is one of the most poorly-vaccinated countries in the world, and that in England, where this method is pursued at the present time, they are having the same trouble with smallpox following vaccination as was experienced in this country some years ago.

Selection of Animals.—Mention was made of the careful selection of animals used in the preparation of this virus in order to exclude the possibility of transmission of infectious diseases and especially tuberculosis, and the technic of the inoculation of these animals was given in detail. Especial stress was laid upon the importance of avoiding drawing blood in vaccination. Many of the complications of vaccination are due to the micro-organisms on the surface being carried into the subcutaneous layers of the skin, thus producing pathogenic conditions. The glycerinized virus he considers far superior to the dry points, as he has observed several cases in calves vaccinated with the dry points where the odor of the animal became very offensive and amount of discharge from the wound very great in three or four days after the operation, while no such conditions have been noted where the glycerinized virus was used.

Dr. R. N. Wilson referred to two cases of tetanus following vaccination which had recently come under his notice, both of which resulted fatally, one in thirty hours and the other in six days after the development of this condition. Both of these cases had passed through a long incubation period and both were treated with antitoxin, which was administered as soon as the symptoms developed. Both were the children of stablemen and both families lived in close proximity to the stables, one of the children sleeping with its father, who was a coachman. The children were vaccinated in the most aseptic manner. As regards the source of infection, the speaker considered it due to outside infection, particularly as this same virus had been used in vaccinating about 560 students at the University of Pennsylvania and not a single case of tetanus has occurred among this number. As a curative agent he is inclined to place but little value upon the tetanus antitoxin, believing that its greatest use is in producing immunity from the disease, in which capacity he considers it invaluable.

Shields.—Dr. C. P. Franklin considers that many of the complications following vaccination are due to shields, and he is at present following out an original idea of always putting on the vaccination as soon as the virus is placed thereon, a little piece, say ⅜ of an inch square, of silk plaster, asepticized and prepared as would regularly be done for other surgical uses. He then puts on a dome-shaped aluminum shield which is also an original idea, the dome being formed by two ribs of the metal. This serves to protect the arm from the heavy winter underclothing and from inadvertent scratching. He has been using this method for some time and has since had no cases of tetanus and very few cases of inflammatory conditions of the arm.

Dr. Hugh Hanna made a few remarks on the subject of tetanus, bearing particularly upon a case of this condition following vaccination which had recently come under his observation. This case occurred in a child and the symptoms developed sixteen or eighteen days after the vaccination. The sanitary conditions were far from ideal, as the house was directly connected with a stable, the door from the dining-room opening into the stable, and the speaker was of the opinion that this, together with the fact that the people were not very careful in their habits, is quite likely to be responsible for the infection. The child was vaccinated on the left thigh. All the typical symptoms of this condition were present, the lockjaw lasted about a week, opisthitonus was pronounced and the convulsions of the muscles would come on at any time day or night. No antitoxin was used, but potassium bromide was administered in twenty- to thirty-grain doses every hour

for four or five hours, when it began to produce its effect, after which it was given on a two-hour basis. There was a small quantity of tincture of opium used in the early stages, but this was discontinued after the first day or two. After the severity of the spasm was relieved, it was observed that the stomach did not seem inclined to tolerate the bromide much longer and other narcotics were then resorted to. This was just prior to the beginning of convalescence. In about three weeks after the onset of the attack the child was able to sit up in bed and be helped up and sit in a chair, and now, several weeks later, she is able to go about the house. Her convalescence has been rapid.

NEW YORK STATE MEDICAL ASSOCIATION.

NEW YORK COUNTY BRANCH.

Stated Meeting, Held December 16, 1901.

The President, Parker Syms, M.D., in the Chair.

Double Fibroid of the Uterus.—Dr. Frederick Holme Wiggin presented two large fibroid tumors that had been removed from a uterus. He also showed other fibroid specimens and stated that he believed firmly that fibroids should be removed whenever they give serious symptoms. He has seen carcinoma of the ovary develop in cases where fibroid of the uterus existed and he has had no doubt that the malignant degeneration was due to the constant irritant presence of the fibroid and the congestion of the tissues which resulted. Malignant degenerations as the result of permitting fibroids to remain he considers to be not a rare sequela. This reason alone would suffice as an indication for their removal even in elderly persons. Deciduoma malignum used to be considered rare. When J. Whitridge Williams in 1895 presented the first American case it was thought a curiosity. The tumors have not become more frequent, but they have been found to occur much more frequently than was thought. Dr. Wiggin presented a specimen of this form of tumor and had some time ago another case in which he suspected its presence. The patient gave a history of having skipped three menstrual periods and then suffered from severe hemorrhage. The bleeding became severe, abortion was suspected and she passed a hydatid mole. The principal symptom for which she came to the hospital had no relation to her uterus, but consisted in severe sciatic pain. Extension of the leg was extremely painful, while flexion gave some relief. Her uterus was found to be about the size of an orange, though perfectly movable. Her condition was considered to indicate curettage. The curette did not bring away much material, but as the result of its use an enormous hemorrhage began. It was the largest hemorrhage Dr. Wiggin had ever seen. A stream of blood the size of the index finger that could not be stopped flowed from the vagina. A clamp was accordingly applied to the uterine arteries and the uterus was removed. This was done without hesitation because of a recent incident in the hospital. A patient on whom curettement was done suffered severely from hemorrhage and before it could be stopped by ordinary methods she was dead. In Dr. Wiggin's case fifteen hundred cubic centimeters of salt solution were introduced into a vein after the operation, and the patient recovered without incident.

Pathologist's Report.—Dr. Jeffreys said that the clinical history of the case, the appearance of the uterus, and especially the immense hemorrhage after the curettement, all point to the presence of a deciduoma malignum. The microscopic character of the growth is not sufficiently typical to make the pathological diagnosis absolute. As all previous cases of deciduoma malignum have proved fatal, because of the malignant invasion of other organs, it is probable that the after-history of this case will clear up the diagnosis. So far there is no lung involvement, though the usual rule is to have metastases of this form of tumor to the lungs. Dr. Jeffreys presented microscopic sections of the tumor and stated that he considered it to be deciduoma malignum in a very early stage. There were marked invasions of the uterine walls by characteristic portions of decidual tissues. These point out the malignancy of the growth and seem to settle all doubt as to its absolute character, though so far these tumors have not been seen at so early a stage as in this case.

Surgical Anatomy of the Lung.—Dr. Irving S. Haynes of New York made a series of demonstrations on the cadaver to illustrate the surgical anatomy of the lung. He pointed out the costophrenic space which in the mid-axilary line begins about the ninth interspace and in the scapular line begins about the eleventh interspace. This is in the living subject and in conditions of health only a potential space. Effusion of fluid displaces the lung and the diaphragm and, hence, creates a space within whose limits there is favorable opportunity for operation. Dr. Haynes pointed out how closely the kidney and the spleen come up under the diaphragm and suggested the surgical possibilities that their relations involved. He pointed out how far the pleura rises up into the neck and indicated its limits at from half an inch to three-quarters of an inch above the clavicle. Dr. Haynes demonstrated the recent operation outlined by a French surgeon for the removal of foreign bodies from the right bronchus. Anatomically this operation is perfectly possible, surgically there seems serious danger of leaving the patient a corpse. The muscles of the back have to be cut through, the ribs resected and, at a depth of over three inches in the tissues, the azygos vein is discovered crossing the right bronchus. Care must be taken not to wound this. After making an opening three inches deep the operation is only just begun and the right bronchus has still to be opened. The operation seems theoretical rather than practical.

Status of Tuberculin.—Dr. E. A. de Schweinitz, Chief of the Biochemic Laboratory at Washington, D. C., sent a paper which was read by the Secretary on the use of tuberculin and of the products obtained directly and indirectly from the tubercle bacillus in pulmonary tuberculosis. The conclusion of experts is that neither the new nor the old tuberculin is effective in therapeutics. Dr. Otis of Boston, who has had considerable experience with tuberculin T. R., says that his faith in the substance as a diagnostic aid has been sadly shaken. In human beings men with outspoken tuberculosis sometimes fail to show any reaction after injections of the tuberculin. This is not true for animals. Very carefully conducted tests on animals show that tuberculin fails to demonstrate the presence of tuberculosis in a very small fraction of one per cent. of the cases. The tuberculin that is used for diagnostic purposes in animals is from human tubercle bacilli. At present these tubercle bacilli have been grown so frequently upon artificial media that they are innocuous for guinea-pigs. The properties of the substance, however, for diagnostic purposes remain unimpaired. With regard to the tuberculin from human and bovine tubercle bacilli, their action upon other animals seems to be about the same. Avian tuberculin seems to be practically identical in its effects with human and bovine tuberculin.

Tuberculin for Prophylaxis.—It is possible that tuberculin may yet be used for prophylactic purposes. Certain very encouraging observations in this line have

recently been made. In animals the continued use of increasing doses of tuberculin gradually renders the animal immune to larger and larger doses of virulent tubercle bacilli. These observations seem to show that the use of tuberculin for diagnostic purposes in human beings is not only permissible, but in suitable afebrile cases may actually prove of service in producing a certain reactive immunity of tissues.

Human and Bovine Tuberculosis.—The question of the distinction between those two processes is of intense interest just now because of Koch's declaration in London last August. Dr. Schweinitz is in the midst of a series of experiments that may help to throw some light on the matter. Monkeys were experimented upon and proved to be more susceptible to bovine tubercle bacilli than to those obtained from human sputum. The baboon, which is more nearly like man than the ring-tailed monkey, which was also used in these experiments, proved to be less resistant, though it is larger in size, and died of general tuberculosis six weeks after the injection of bovine tubercle bacilli. The smaller ring-tailed monkey lived for eight weeks and the infection was not so general.

Antituberculous Serum.—Serum prepared from the blood of animals injected with increasing doses of virulent tuberculous material has been used with some success in certain cases. Results have been so encouraging at times that the question of its possible usefulness must not be lost sight of. Tuberculosis, however, is a disease in which it is extremely easy to be self-deceived with regard to therapeutic effects. It will take a long time before the question of the absolute usefulness of this remedy can be decided.

Dr. J. Edward Stubbert of Liberty, N. Y., read a paper on the "Early Diagnosis of Pulmonary Tuberculosis with X-Ray Pictures of Diseased Lungs." This paper will appear in a subsequent issue of the MEDICAL NEWS.

Surgery of Pulmonary Tuberculosis.—Dr. William G. LeBoutillier said that it has always seemed as though surgery ought to be of practical use in tuberculosis of the lungs. At first it was thought that the introduction of drugs into cavities would prove curative. Then, too, it was considered that actual drainage of septic materials might be secured with the production of artificial collapse. After some unsatisfactory observations, however, the injection of chemicals was abandoned. Recently benefit has been derived from the injection of iodoform introduced through an incision in cases in which microscopic diagnosis demonstrated the existence of tubercle.

Nitrogen Injections.—These are now under trial. Favorable results have been reported. Undoubtedly this is an imitation of Nature's method of curing tuberculosis. Where small, limited areas of tuberculosis exist they would be especially suitable for extirpation. These are, however, just the cases that get better under simpler methods. If there is pyogenic infection and secondary symptoms occur, then surgery should be thought of. Aspiration and injection of cavities have not proved satisfactory, probably because the incision was too small. Obliteration of cavities is Nature's method of curing tuberculosis. Often, however, obliteration of the cavity fails, because the lungs are adherent and so collapse of the walls of the cavities cannot occur. Surgery may do good here by freeing the lungs from adhesions, and especially is this liable to do good where there is a single large-sized cavity. The injection of nitrogen gas should be employed whenever there are no adhesions. Hemorrhages can be treated very satisfactorily by means of nitrogen injections.

Treatment of Tuberculosis.—Dr. Charles E. Quimby said that when patients become ill with tuberculosis physicians are apt to send them to nearby sanitaria. When they themselves get ill they pack up and go to Denver. The climatic treatment of tuberculosis is undoubtedly the most effective. If patients insist on staying in the city we have no specific treatment, but we can do much to help them. There are two principal indications: First, increase the systemic defense, and, second, minimize the offensive forces. It is important to induce as soon as possible a high grade of nutrition. Patients should live high and develop gout as soon as possible. Patients with gouty tendencies do not develop tuberculosis. For this purpose tonics are necessary. Warburg's tincture is a good remedy. The use of the alteratives, especially mercury and arsenic, is to be recommended. Because of hepatic stimulation some form of oil should be taken rather frequently. If there is fermentation in the intestine, with tendency to colicky pains and diarrhea, castor oil should be used. Otherwise olive oil should be employed in tablespoonful doses three times a day or oftener. For stimulation of the general circulation hydrotherapy is extremely important. After the application of water dry friction should be employed. Any one who has seen how effectually a hacking cough can be relieved by a brisk rubbing of the thorax, back and buttocks, will never neglect the use of this therapeutic measure. The pain of dry pleurisy can also be removed in this way. The resolution of the inflammatory process on which dry pleurisy depends can also be hastened by the stimulation of the peripheral circulation.

Pneumatic Cabinet.—For the arrest of hemorrhage, treatment in the pneumatic cabinet is extremely effectual. Patients who are coughing up blood are relieved almost immediately by treatment in the cabinet. The inhalation of the vapors of alcohol formalin and of ozone gas is a useful remedy. The hanging-up in a sleeping-room of cloths that have been wrung out in alcohol and formalin does good to the patient and at the same time probably renders the rooms less dangerous for other people.

Tuberculous Patients at Lakewood.—Dr. William G. Schauffler of Lakewood, N. J., said that physicians are entirely too careless in sending patients with incipient tuberculosis away from home. If a patient is moderately well to do and his physician discovers that he has a tuberculous focus in his lungs, it is the custom to tell him briefly that he must go away from home for a time and take care of himself in the country. Lakewood is suggested as one of the possibilities for this stay away from home. The patient is told that he must stay out of doors most of the time, but nothing is told him of the inclemencies of the climate at Lakewood. At this season of the year it is no unusual thing to have a difference of fifty degrees between two successive days at Lakewood. For this sort of thing the patient is utterly unprepared. In his rather run-down condition with tendencies to fever and an appetite that is not very good, the patient, if he exposes himself, is very apt to be brought down with a congestive chill. As the result of this his tuberculosis is relighted up. He has to keep to his room for some time, his appetite is seriously disturbed and in general his condition is worse than it would be at home. When he does get out some of the precious time of his outing from the city is already gone by with harmful rather than beneficial results. It is too much the custom for city physicians to tell patients that in a short time they will be better. This is all right if the idea is to encourage the patient, but if the person has but

very little money he may easily go to Lakewood with the notion that a few weeks of stay will improve his condition so much that he can return to the city with safety. At the end of a few weeks he finds scarcely any improvement and, as Lakewood is an expensive place, all the money that he can afford to spend on a stay away from home is gone. As a rule, patients should not be sent to an expensive health resort when they may be more comfortable at home. Physicians at Lakewood see the inadvisability of this almost every day.

Home Treatment.—Dr. Schauffler insisted very much on individualizing the advice that must be given to patients. This must vary especially with the pocket-book of the sufferer. Wealthy patients can be readily advised to leave home for an unlimited time; but patients in moderate circumstances are apt to feel the drain upon their resources if their stay is to be long continued at an expensive hotel. For poorer patients it is absolute nonsense to make them dissatisfied by suggestions that they cannot follow, or to tempt them to raise a sum of money that will enable them to stay so short a time at Lakewood or some other expensive place that practically no good will result.

The X-Rays in Diagnosis.—Dr. Henry P. Loomis said that his experience with the X-rays in the early diagnosis of incipient tuberculosis did not quite bear out Dr. Stubbert's statement. The use of the fluoroscope does not make it possible to recognize tuberculous conditions until considerable thickening has occurred. By this time the disturbance of respiration and especially prolonged expiration will have become noticeable. The X-rays are of avail in assisting one to map out cavities better than by percussion. Dr. Loomis' experience with tuberculin in the diagnosis of tuberculosis has been very bad. He has been fearful of the results in some cases and has failed to obtain reaction in certain well-marked cases of pulmonary tuberculosis. The method of diagnosis with tuberculin is entirely too dangerous, considering how little advantage is to be gained from its use even under the most favorable circumstances. While the use of the method by such conservative observers as Trudeau shows that when carefully employed it may be of service, it is by no means a method for general employment. For the early diagnosis of initial lesions of tuberculosis in the lung, certain localized areas besides the apices should be carefully examined. The physician should never neglect to listen at the root of the lungs where the smaller bronchi are given off. It is in the smaller bronchi that the tuberculous processes usually begin. Auscultation of the root of the lung may be practised to best advantage by having the patient put the palm of his hand on the opposite shoulder. This raises the scapula and exposes a portion of lung that is often affected in incipient cases of tuberculosis, before other parts show any sign of the affection. Physical signs will often be found here long before bacilli occur in the sputum.

Prognosis of Tuberculosis.—As the result of association with sanitaria in which it is advisable that patients should if possible get well within a year, so as to leave places for other patients, Dr. Loomis' attention has been especially directed to the prognosis of incipient cases of tuberculosis. The most important factor for a patient in this matter is his stomach. A bad stomach always means a bad prognosis. This does not mean that the case is hopeless because a cough mixture easily disturbs the patient's stomach. What is meant is that patients who suffer easily from indigestion have an unfavorable outlook. The occurrence of rapid heart at the begining of a tuberculosis when the physical signs are very slight is a bad sign. This shows an instability of the nervous system controlling the circulation, and the patient's future depends to a great extent on his circulation compensating for his pulmonary lesions. If, with a slight apical catarrh, a patient has a pulse-rate of 105 to 115, the prognosis is never good. Such patients are slow to improve and relapses are rather frequent. If, notwithstanding the fact that their tuberculosis is in its incipiency, patients continue to lose in weight under careful treatment the prognosis is not good. The cure of tuberculosis depends to a large extent on the patient putting on weight. If they have no tendency to do this in the early stages of their disease, it is a sign that their internal metabolism is not of the kind that will enable them to compensate for the drain upon their forces due to the presence of a focus of infection in their tissues. Except where heredity is a very prominent factor in the disease and a number of the patient's relatives have died from tuberculosis, simple inheritance does not seem to make the prognosis unfavorable. Vital resistance to tuberculosis is largely a personal rather than a family matter. Patients of a cheerful disposition get along best. There is a tradition that all cases with tendencies to pleurisy do well. Tuberculous affections at the base of the lung are apt to do badly.

Blood-Pressure as an Incipient Symptom.—Dr. S. A. Knopf said that an important symptom of early tuberculosis that may be recognized long before any physical signs are present is a drop in the blood-pressure. According to Professor Potain of Paris this was one of the most important diagnostic signs of the early stage of tuberculosis. It occurs long before any other sign and may be obtained readily with a manometer especially made for this purpose. Dr. Knopf's experience with tuberculin has been very sad. He does not think that any material for diagnostic or remedial purposes should be used by a physician on patients unless he would be willing to have it used on himself. Very few physicians would be entirely willing to have tuberculin used on them merely for diagnostic purposes.

Sanatorium at Home.—Sanatorium treatment at present is only possible for the wealthy and for those better provided with pecuniary means. The great mass of the people who become ill with tuberculosis must be treated at home. For them the great lesson of the open-air treatment at home is important. If nothing better than a steamer chair can be procured they should recline on this on a balcony in the open air for most of the day. If the balcony is out of the question, then they should sit at an open window even during the winter. The other element in the successful treatment of tuberculosis at home is the absolute regulation of every moment of the patient's life and of every portion of his dietary. Undoubtedly, hydrotherapy is of great benefit in tuberculosis. For its efficacious employment, however, an expensive bathing establishment is not necessary. Even a bath-tub can be dispensed with if none is at hand. Friends of the patient may be instructed to pour pitchers of cool water over him and the practice of massage and rubbings with alcohol will complete the stimulating influence upon the peripheral circulation which means so much to tuberculous patients.

WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Eleventh Annual Meeting, Held in Chicago, December 18 and 19, 1901.

The President, A. F. Jonas, M.D., in the Chair.

Old Shoulder Dislocation with Report of a Case.—

Dr. J. Rudis-Jicinsky of Cedar Rapids, Ia., presented a paper on this subject, showing the work of the X-ray in injuries to the joints, in luxations, fractures, the growth of callus, etc. He said in closing that one could period, when the organisms disappear, is still a exact position of the fragments.

Irreducible Backward Dislocation of the Astragalus.—This subject was discussed by Dr. W. Jepson of Sioux City, Ia. He did not believe it was possible to bring about the reduction of a backward dislocation of the astragalus without opening the joint and bringing about a reposition of the bone by direct manipulation. The astragalus should only be removed where the bone is completely separated from its ligamentous attachments.

Internal Injuries of the Knee-Joint.—Dr. M. L. Harris of Chicago referred to two varieties of injuries to the inner structures of the knee-joint, which he believed were quite common, and reviewed the ways in which the injuries could be received and the operative treatment.

Ankylosis of Joints.—Dr. John B. Murphy of Chicago recommended arthroplasty for the relief of ankylosis. He would treat such joints as one would treat non-union of fractures, as suggested by Chlumsky, from the interposition of foreign material between the fragments. He had employed the method successfully.

Treatment of Dislocation of the Clavicle Through Open Wound.—Dr. James B. Moore of Minneapolis, Minn., read a paper on this subject. Quite recently he had treated a case by cutting down upon the dislocated bone, replacing it and the surrounding soft parts and fastening them by means of silver wire and catgut sutures. The result was very satisfactory.

Etiological Factors in the Production of Tumors.—Dr. George Halley of Kansas City, Mo., referred first to the literature on the subject, including its etiology. He differentiated the processes of inflammatory conditions and tumor growths, and said that inflammation, because due to irritation, was the prime factor in the production of morbid growths.

Surgical Procedures in the Removal of Fibromyoma of the Uterus.—Dr. Joseph Eastman of Indianapolis, Ind., believed that the morphology of the tumor and environment of the patient should first be considered before removing the tumor.

Myomectomy; Its Place in the Treatment of Fibromyoma of the Uterus.—Dr. O. Beverly Campbell of Chicago, said that myomectomy can only be applied to well-selected cases, but should be the preferred method in every case where possible without risk to the patient and where the ovaries can be conserved with the uterus. Operative interference should be advised wherever myomectomy is possible; it is safe and free from risk.

Management of Uterine Fibromyomata Complicated by Pregnancy.—Dr. Miles F. Porter discussed the subject. Pregnancy he considered a serious and frequent complication of uterine myofibromata; each case was a law unto itself and should be treated accordingly. Of the utmost importance are the life of a mother and of the child.

The Treatment of Fibroids of the Uterus by Electricity.—This was the title of a paper by Dr. Franklin H. Martin of Chicago. He was of the opinion that the evolution of surgery for fibroids had gradually reversed the relative position of the galvanic treatment; that vaginal and abdominal hysterectomies and myomectomies for fibroids giving rise to serious symptoms, with their legitimate mortality reduced to one and two per cent., are remedies more conservative in their results than the treatment of the same tumor by electricity. While electricity frequently relieved, it seldom removed a tumor, and he believed that it had been properly superseded by surgery.

Discussion.—Dr. W. O. Henry of Omaha, Neb., thought that the electrical treatment of these tumors was overdone. Dr. Van Buren Knott of Sioux City, Ia., was of the opinion that myomectomy was a conservative procedure. Dr. B. B. Davis of Omaha, Neb., said that in case of myoma complicating pregnancy the tumor should be removed before the woman became pregnant. He condemned the induction of abortion before delivering or removing the tumor. Dr. C. H. Mayo of Rochester, Minn., mentioned the case of a woman of thirty years upon whom he had operated for tumor complicating her first pregnancy. She made a good recovery. Dr. A. C. Bernays of St. Louis, Mo., was in favor of myomectomy. Dr. Charles H. Wallace, of St. Joseph, Mo., believed that myomectomy was comparatively easy, but Dr. J. N. Warren of Sioux City, Ia., did not think that it was an easy operation. Dr. W. A. Tichenor of Chicago considered myomectomy a formidable operation. Dr. James E. Moore of Minneapolis, Minn., referred to the possibility of doing myomectomy through the vagina.

The Use of the Gall-Bladder as a Suspensory Ligament for Prolapsed Liver.—This was the title of the presidential address by Dr. A. F. Jonas of Omaha, Neb. He said that the liver was sometimes displaced downward to a considerable degree and that there was generally modified function and a definite clinical picture. He narrated the case of a woman who had suffered for three years from paroxysms of severe pain in the right hepatic region. On operation the liver was found three finger-breadths below the costal arch; in appearance it was normal. The gall-bladder was found with calculi in its walls. A displaced and movable kidney was likewise found. The gall-bladder was used as a suspensory ligament. The wound closed nicely and the patient was directed to wear a snugly-fitting abdominal band.

Heart Suture.—Dr. B. Merrill Ricketts of Cincinnati, O., read a paper on this subject. He had conducted many experiments on animals with reference to suturing the heart. Of twenty-seven cases of suture of the heart for wounds in human beings, at present noted, seven recovered. He had employed kangaroo-tendon in ligating the coronary arteries and fine silk sutures in the walls of the heart, as it was necessary to use a long-lived catgut. He believed that the time had come when a surgeon should no longer hesitate to open the chest for serious injuries of the lung and heart.

Fracture of the Metacarpal Bones and Oblique Fracture, Simple or Compound, of the Forearm.—Dr. W. W. Grant of Denver, Col., presented this paper. He referred to the application of Buck's extension in fractures of the femur, forearm and hand, and certain inflammatory conditions of the wrist and elbow-joints.

Total Extirpation of the Prostate Gland Through a Median Incision in the Perineum.—Dr. Alexander Hugh Ferguson of Chicago reported several cases operated upon by himself in which the results were better than had ever been secured by the suprapubic route. He described the technic of the operation and said that hemorrhage was avoided so long as one was careful to work within the capsule.

Symptoms, Signs, Diagnosis, Prognosis and Palliative Treatment of Hypertrophy of the Prostate.—Dr. Lewis Schooler of Des Moines, Ia., read a paper on this subject. In considering the palliative treatment he mentioned massage, aspiration, catheterization, dilatation and cystotomy. He made a plea for advance in therapeutic resources.

Pathology and Etiology of Prostatic Hypertrophy and Suprapubic Drainage as a Method of Treatment.—Dr. A. C. Bernays of St. Louis, Mo., presented this paper. The essayist believed that suprapubic cystotomy in stone in the bladder, hypertrophy of the prostate, etc., was a recognized and successful method of treating those conditions. By means of the drain he could give entire physiological and mechanical rest to the bladder, which rest would have a beneficial effect upon the hypertrophied prostate. However, he was of the opinion that as a radical cure for prostatic hypertrophy suprapubic drainage was a failure. He was opposed to operations in the dark.

Suprapubic Prostatectomy.—Dr. C. H. Mayo of Rochester, Minn., read a paper on this subject and said he believed that one-half of the enlarged prostate could be equally well reached from above or below, one-fourth better from above, one-fourth better from below, and a few would require a combined operation.

The Indications and Limitation for the Bottini Operation.—Dr. Louis E. Schmidt of Chicago read an interesting paper in which the writer concluded that the good results of the Bottini operation depended on the correct selection of cases, the proper technic of the operation and proper after-care, and the immediate correction of errors and misbaps.

New Method of Anchoring the Kidney.—Dr. Byron B. Davis of Omaha, Neb., read this paper. The author described very minutely the technic of his operation and gave the history of a case, saying that he reported the matter because it represented a new principle in treatment.

Intestinal Obstruction from Meckel's Diverticulum, with Recovery.—Dr. A. E. Halstead of Chicago summarized all cases accessible to him that could be found in literature. The total number of cases reviewed was 72; males, 45; females, 17. Deaths, 44. Recoveries, 21. Attachment or non-attachment of diverticulum or diverticular ligament, mentioned in 66; point of attachment noted in 44; to mesentery in 21; to umbilicus in 14; not determined in 3; diverticulum attached, 47; diverticulum free, 19.

Grave Abdominal Injuries without External Evidences of Traumatism.—Dr. R. Harvey Reed of Rock Springs, Wyoming, presented a paper on this subject. It is the surgeon's duty to make an exploratory incision in all cases where there is real doubt as to the nature of an injury and particularly so when the constitutional symptoms pointed to a condition more serious than was indicated by either the subjective or objective symptoms.

Dr. A. W. Abbott of Minneapolis, Minn., had experimented largely on animals with a view to determining the immediate effects of intestinal exposure. He concluded that the loss of water was unimportant, that the loss of heat was very important, as it temporarily placed the temperature of the intestines below the safety line, and that the drying of the peritoneum was so decided as to disturb the normal anatomical relations.

Our Hospitals.—This was the title of a paper by Dr. H. D. Niles of Salt Lake City, Utah. He believed that so long as a hospital measured its own usefulness by the number of patients treated, the standing of each member of the staff would be largely estimated by the size of his personal following, and the commercial spirit would rule both the institution and the individual to the exclusion or great detriment of scientific work. If the profession was ever to secure a voice it should formulate and adopt a business code that should not only meet the highest requirements of the ethics of the profession, but, at the same time, command the respect and win the confidence and support of the twentieth century public.

Surgery of Spina Bifida.—Dr. Van Buren Knott of Sioux City, Ia., read this paper. The clinical features, diagnosis, prognosis and treatment were discussed. He also reported four cases, and was of the opinion that meningoceles, meningomyeloceles and syringomyeloceles may be considerably benefited by operation.

The following officers were elected for the ensuing year: President, Dr. James E. Moore, Minneapolis, Minn.; First Vice-President, Dr. J. R. Hollowbush, Rock Island, Ill.; Second Vice-President, Dr. W. W. Grant, Denver, Col.; Secretary-Treasurer, Dr. George H. Simmons, Chicago, Ill.

The next meeting will be held in St. Joseph, Mo., December 29 and 30, 1902.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK

Stated Meeting, December 23, 1901.

The President, Frank Van Fleet, M.D., in the Chair.

Etiology and Pathology of Osteomyelitis.—This first paper of the evening was read by Dr. Joel E. Goldthwaite of Boston, Mass. Osteomyelitis is an acute infectious process always going on to suppuration and due to the presence of some microbic agent within the bone. It has been suggestively described as furunculosis of bone. In the ordinary skin furuncle a hair follicle becomes infected by pus micro-organisms. This produces the usual manifestations of inflammation. Leucocytes are poured out around the inflammatory focus, and this is walled off from absorption into the system. After a time the inflammatory exudate becomes fluid and as it is near the surface forces its way out with spontaneous evacuation of the infective material. Owing to the position in which pus develops within the bone shaft, it is retained, cannot find any avenue of exit, and so in osteomyelitis there is danger of general infection. Not infrequently the purulent process spreads at least through the bone marrow itself, producing quite extensive inflammation. At times, however, it remains as an absolutely localized process and may for years produce intermittent effects of discomfort and positive pain simulating joint disease. Dr. Goldthwaite then detailed some typical cases of osteomyelitis to illustrate its etiology and pathology.

Osteomyelitis After Measles.—The patient was a lad, six and one-half years of age, who shortly after an attack of measles was taken with a sharp pain in the upper part of the tibia. This became intense and swelling of the parts ensued with spreading of the area over which the pain was felt. The Roentgen rays showed that the whole of the upper part of the tibia had become separated as a sequestrum from the lower part. This type of extensive bone involvement is not infrequent. In this case it was due to the presence of the streptococcus in pure culture. This is the type of disease that is more particularly described in the textbooks, but there are others much less classical in character.

Localized Osteomyelitis.—A child, eight years of age, came to the hospital with a history of having fallen on the stairs. It was thought that he had sprained his ankle. After a few days both ankles became swollen and tender and then it was thought that the child was suffering from rheumatism. The Roentgen rays showed the presence of a localized abscess in the lower part of the tibia on one side and of localized abscesses in the tibial malleolus and in the os calcis on the other side. Though these two abscesses were situated so close together they were due to different causes. From one of the abscesses was obtained

a pure culture of staphylococcus aureus. This abscess was situated in the os calcis and contained yellow, creamy pus. The abscess in the tibia contained whitish pus in which was found staphylococcus albus in pure culture. Most of the clinical differences that are noted in osteomyelitic processes are due to differing varieties of micro-organisms which cause them. As a rule, the streptococcus produces serious diffuse conditions. The staphylococcus causes much more limited suppuration and, as a rule, a well-defined abscess. The staphylococcus aureus is the most frequent micro-organism in the production of osteomyelitis, as it is also the most common of the ordinary pus micro-organisms. Out of 130 cases of osteomyelitis carefully examined by bacteriological methods, 103 cases contained staphylococcus aureus.

Other Micro-Organisms.—Not infrequently the pneumococcus causes osteomyelitis. The pathological process occurs shortly after a pneumonia and runs a very rapid course. The pneumococcus has a very curious tendency to affect the epiphyseal ends of the long bones. The typhoid bacillus is rather more frequent than the pneumococcus in producing osteomyelitis. Keen, in his monograph on the surgery of typhoid fever, collects 38 cases of typhoid (pure culture) osteomyelitis. Other micro-organisms also produce osteomyelitis. In one case Dr. Goldthwaite found the *bacillus fœtidus*. As a matter of fact, osteomyelitis is not a specific disease, but may be due to almost any micro-organism or to mixed infection.

Incidence of Osteomyelitis.—About one-half the cases of the affection occur between the ages of thirteen and seventeen. It is considerably more frequent in boys than in girls. The reason for this is not far to seek. Boys are more subject to injuries in their sports than are girls. Osteomyelitis occurs especially after exhausting disease, as after diphtheria or after the exanthemata. In these cases it is due not to the micro-organism that causes the disease, but to a secondary infection. Usually there is a history of some slight injury to account for the localization of the lesion.

Avenue of Entrance.—Osteomyelitis is not infrequently secondary to a furuncle or a small ulcer. The micro-organisms seldom seem to find their entrance through the intestinal tract, though from the occurrence of pneumococcus osteomyelitis, it is evident that the lungs are not so capable of keeping out infection. Ullmann showed that animals fed with large quantities of bacteria, mainly pus micro-organisms, did not suffer from osteomyelitis, even though fractures of their bones were artificially produced with the idea of causing a localization of the purulent infectious material in them. Dr. Goldthwaite is of the opinion that spinal osteomyelitis is much more frequent than has been thought. The laminæ are much more liable to be affected than the bodies of the vertebræ. Many of the reported cases of cured spinal caries without deformity are really instances of osteomyelitis of the vertebræ. An osteomyelitic abscess may produce spinal cord pressure and paralytic symptoms.

Chronic Osteomyelitis.—Dr. Goldthwaite has had a case in which some soreness in the neighborhood of the joint, but really localized in a long bone, occurred not long after typhoid fever. At irregular intervals, sometimes of months, sometimes of years, there were subsequent attacks. The pain was usually referred to the knee. Careful examination finally revealed the existence of a localized area of tenderness over the head of the tibia. On operation a localized abscess was found, probably due to the attack of typhoid fever over thirty years before.

Symptoms of Osteomyelitis.—Dr. Robert Tunstall Taylor of Baltimore, Maryland, read a paper on the clinical aspects and differential diagnosis of osteomyelitis. He said that his attention had recently been called to a chapter on the symptomatology of osteomyelitis written by the elder Nathan Smith of Yale more than 100 years ago. This gave such a complete idea of the symptoms and clinical course of osteomyelitis and was so exactly the same as might be written at the present moment that Dr. Taylor scarcely felt that he had a right to present the subject anew. The premonitory stage presents no very definite symptoms. There is apt to be some malaise and apathy, as the result of the absorption into the system of infectious material. After these uncomfortable feelings have continued for some time, there is apt to be a profound chill or, in children, a convulsion. Severe constitutional symptoms may follow these preliminary manifestations. There may be metastases of septic material to the meninges or to the heart, or there may be septic or fat emboli in the brain, causing sudden death.

Active Osteomyelitis.—Usually the most prominent symptom of the active stage of the disease is excruciating pain which is described by patients as of an intense, boring character. This is due to the fact that the pus is confined. As soon as it succeeds in finding its way out of the bone into the soft tissues, or when it is evacuated in any other way, there is an immediate sense of relief. The most useful symptom is tenderness. This is usually localized, but may be diffuse if the process has existed for some time. The osteomyelitis usually occurs in the long bones and especially those of the lower extremity. But it may occur in the flat bones and is not infrequent in the sternum. It occurs much more frequently in the bones of the spinal column than has been thought. The parts immediately over the osteomyelitic area do not become red and hot unless the pus finds an exit through the bone and approaches the surface. It is important to remember that pus microbes may exist in bone marrow for twenty years, only producing occasional symptoms of not very serious character, and then, finally, there may be a relighting up of the inflammatory process with severe symptoms.

Differential Diagnosis.—The important aid to differential diagnosis is the use of the Roentgen rays. The bacteriology of the blood is, however, also of importance. Frequently the bacteria will be found free in the circulation if the symptoms are generalized. Leucocytosis is always present in osteomyelitis and this enables us to differentiate it rather easily from typhoid fever, or scurvy or begining sarcoma. Dr. Richard Cabot of Boston says that the blood in osteomyelitis is of more diagnostic value than any other element. In rheumatic pains, growing pains and the like, which sometimes, when very severe, arouse suspicion of the existence of osteomyelitis, there is no leucocytosis.

Tuberculous Joint Affections.—Dr. H. Augustus Wilson of Philadelphia read a paper on tuberculous, rheumatic and other affections of the joints, especially with reference to their etiology, pathology and differential diagnosis. He said that one of the most prominent features in tuberculous joint disease is the existence of tuberculous heredity in a very large majority of the cases. While the tuberculosis may not be congenital in any true sense, it is probably acquired at a very early age from association with tuberculous relatives. In early stages of tuberculous joint disease, the bacilli in the inflammatory products of the joint lesions take very well the ordinary stains for tubercle bacilli. Later they fail to take the stains so well. Finally, after considerable degeneration has taken place, the caseous material presents no signs

of the existence of tubercle bacilli when staining materials are used. Often when such degenerated tuberculous material is injected into animals, it fails to produce tuberculosis. In the course of time the mass has become non-infectious. This is the idea on which is founded the present system of therapeutics for these affections. If the parts are set at rest long enough Nature is able to protect herself and gradually to make the nodule of tuberculosis innocuous. The most important point in the treatment of tuberculous joint disease is its early diagnosis; the sooner the affected parts are put at rest, the surer and the more completely will the lesions heal. Unfortunately, the early diagnosis of tuberculous joint disease is not so easy as might appear in the perfectly characteristic symptoms that occur when the lesions are well developed. Very often the triviality of the symptoms at the beginning blinds the physician to the serious nature of the process that is at work. Orthopedic specialists are apt to blame the family physician for delay in the diagnosis of these conditions, but it is often almost impossible to recognize them at the beginning.

Referred Symptoms.—Another difficulty in diagnosis is the fact that the symptoms are rarely referred directly to the joint involved, but to some more or less distant part. The nerve to the joint and the muscles that pass over it are the physical basis for these reflex symptoms. Muscular rigidity and pain around a joint must always be considered significant. Night cries, due to the fact that the muscular rigidity, which during the day saves the patient from pain, is relaxed at night with the result of contact of diseased bone surfaces that causes pain, are often an early symptom. They occur especially in the early part of the night, before the child gets into its deepest sleep. Wasting of the muscles around the joint often develops very early in the disease. Within a week or two after the first appearance of joint symptoms some wasting of the muscles may be noticed. The characteristic spindle-shape of the joints, when muscle atrophy has occurred, is often referred to an enlargement of the ends of the bones that make up the joint. Measurements in comparison of the joints on both sides, however, will show that the enlargement is only apparent and due to the muscle atrophy above and below the joint, making it appear larger.

Painful Symptoms.—If there is a suspicion of tuberculous disease of the spine, the patient should be tested by slight jars upon the head. If in a joint in the lower limb, he should be asked to come down on his heels. This will show the existence of tenderness in the spinal or leg joints and constitutes an important symptom. These painful symptoms are so often relieved very early in the treatment by immobilization that the immobilizing apparatus is abandoned very early and the physician has recourse to massage or some other method of treatment. This is always a mistake and must be carefully avoided.

Treatment of Tuberculous Joints.—Dr. A. M. Phelps of New York said that for treatment of hip-joint disease patients should wear the long splint that takes all the weight off the hip-joint. This splint should extend two and a half inches below the hollow of the foot, and the weight of the body should be supported on a padded ring attached to the splint. Before the splint is applied the deformity must be overcome. Contraction of the limb should be overcome by forced extension if necessary. Muscular contraction must be overcome by the application of constant extension. These immobilizing splints for tuberculous hip-joint disease should be worn for from eighteen months to two years. Then a walking splint should be applied which allows of some motion in the ankle, but keeps the hip-joint stiff. To attempt to relieve these cases of the necessity of wearing a splint for a shorter time than this is to invite failure in the treatment and relapse. This apparatus suggested by Dr. Thomas in England makes an excellent splint for knee-joint disease. The patient may be allowed to walk; the splint must come down some two and a half inches below the foot and should be slung over the patient's shoulder. By the use of straps some extension should be applied and by means of other straps the tibia should be pulled well forward.

Aluminum Corsets.—Dr. Phelps exhibited an aluminum corset, light yet strong and so perforated as to secure thorough ventilation. This he considers better than any other apparatus for Pott's disease. It costs more at first, but it will last for ten years, even with reasonably hard usage.

Tuberculous Abscesses.—Whenever there is pus present abscesses should be freely opened and drained. They should not be packed. The inside of the abscess should be thoroughly examined by the finger and all broken down material should be removed. Purulent material should not be allowed to burrow into the muscles and especially not into the tissues around the the rectum, as it produces serious complications. Dr. Phelps uses large speculum drainage-tubes into which a certain amount of material is packed and the tube is allowed to remain in place. When the packing material is removed a good view can be obtained of the affected tissues. These abscesses should be washed out with pure carbolic acid followed by alcohol. This treatment will very often bring a long course of suppuration to an end.

Conservative Treatment.—Dr. Judson said that there is no short-cut to the treatment of tuberculous osteitis of joints. Yet if properly treated these conditions do recover. In a certain sense they are self-limited. Mechanical treatment is of great assistance, because, if the osteitic process is not interfered with, it never becomes serious. The great principle must be *non nocere*. It must be remembered, too, that the child's growth is of great assistance to us in the cure of the tuberculous process. Time is the most important therapeutic element.

Subacute Osteomyelitis.—Dr. George R. Fowler of Brooklyn said that, in spite of the fact that osteomyelitis is usually due to pyogenic micro-organisms, it may run a slow subacute course. This makes the differential diagnosis from tuberculous osteomyelitis difficult. In one case in the sternum after the diagnosis of tuberculous osteomyelitis had been made, the staphylococcus was found to be present, in spite of the chronic course. In the treatment of tuberculous abscesses and especially of chronic suppurative conditions in bones, Dr. Fowler has found that in cases where recurrence is to be feared and where it is often a source of great annoyance to the surgeon and his patient, the use of pure carbolic acid may be of great assistance. After thorough curettement the cavity is filled with pure carbolic acid and then this is lifted out with a pipette. After this alcohol is poured into the cavity and is removed. The pressure of the clot as suggested by Shrady then assists in the reparative process.

Osteomyelitis of Spine.—Dr. Royal Whitman said that acute limited osteomyelitis of the spine is much more common than has been thought. It usually goes on to rapid healing after the pus has found an exit, and these are the cases of so-called Pott's disease that heal without deformity.

Osteomyelitis Not Rare.—Dr. Willy Meyer said that acute osteomyelitis is not rare in this city. If

embolic septic pneumonia occurs in connection with it and other general symptoms it is not easy to detect its presence. A source of infection that is sometimes not considered in these cases is the use of septic dental instruments. More than one-half the dentists in the city either take no antiseptic precautions, or take precautions that are so incomplete as to be of no avail. It is often from suppurative processes within the mouth that osteomyelitis is set up. Dr. Meyer said that in treating tuberculous joints in the arm Beer's method of producing venous congestion by means of elastic constriction should not be forgotten. Dr. Meyer has had a number of cases in which this method of treatment has given excellent satisfaction.

Syphilitic Element.—Dr. Plympton said that in cases of osteomyelitis with tendency to recurrence there is often a syphilitic basis to the disease. In relapsing cases mercury and the iodides should be used freely and will often be found of service. Frequently these cases are due to congenital syphilis and there may be very little to lead one to the suspicion of the existence of this disease.

SOCIETY OF DERMATOLOGY AND GENITO-URINARY SURGERY OF NEW YORK CITY.

Stated Meeting, Held December 13, 1901.

The President, Robert H. Greene, M.D., in the Chair.

Cutaneous Favus.—Dr. E. L. Cox presented a patient suffering from a characteristic lesion of favus on the left forearm. When the patient, a girl about twelve years of age, came for treatment some four weeks ago, she complained of an abrasion on her arm. The characteristic appearances at once pointed out the diagnosis and a history of contact with animals was soon obtained. The little girl was accustomed to play with a cat. There was also a history of a mouse running around the house, apparently so tame that it allowed itself to be caught by members of the family and the little girl had handled it. The mouse disappeared shortly before the little patient came under treatment. It seems not improbable, however, that instead of being tame the creature was really blind. Careful questioning elicited the fact that it had something peculiar about its head. It is probable that it was suffering from favus, which it communicated to the little girl either directly or through the cat. Scrapings from the lesions produced beautiful cultures of characteristic cauliflower-shape when grown upon potato. Treatment of the condition is, of course, easy and it will not be long before the lesions will be made to disappear definitely.

Chancroidal Lymphangitis.—Dr. De Villa presented for Dr. Ramon Guiteras a case of this rare affection. Seven weeks ago the patient had coitus followed in two weeks by sores, three in number, under the prepuce. These caused a phimosis. He then presented himself at the clinic. His prepuce was then still phimosed, very much elongated, edematous, and infiltrated. The whole organ was red and the lymphatics on the dorsum of the penis were much enlarged, thickened and nodular. The pain was severe. One week later the lymphatics broke down, forming three ulcers upon the dorsum of the organ. These were typically chancroidal in character. The ulcers were cauterized and are healing. The patient can now pull the prepuce back a little. He has been injecting black wash beneath the prepuce and also using the lotion between its edges and to cleanse the chancroids on the dorsum of the penis. The lymphatics of the groin have become slightly enlarged during these last few days.

Bubonuli.—In discussing this case Dr. Leviseur said that the lumpy formations on the dorsum of the penis which finally break down are really bubonuli, little buboes. The lymphatics of the dorsum of the penis sometimes catch and retain the infectious agents from the chancroid, particularly if the original chancroid is located underneath an elongated and phimosed prepuce. It is not surprising, then, that a pathological condition should develop similar to that which occurs in ordinary buboes. The swellings are usually smaller in size and break down much more easily, forming crater-like ulcers as in this case. Quite often the occurrence of buboes in the groin is delayed until late in the affection and this seems to have been the case also in the present instance.

Favus of the Nails.—Dr. Leviseur presented the nails removed from a case of favus of the nails and showed a wax cast of the fingers before treatment. The patient was a nurse, twenty-one years old, born in Ireland, who had suffered from an affection of the scalp for six years. Four months ago the nail of the index finger of the left hand began to show symptoms of disease and one month later the third finger was likewise affected. The condition is characterized by the absence of some part of the nail plate and an irregular hypertrophy of the nail bed whenever the horny layer is missing. The border of the latter is undermined particularly in the center where there is a hollow space which almost reaches the lunula. The diagnosis favus

Favus of Nails.

was made and on examination of the scalp, two bald, irregularly oval spots occupying the top of the head were found. They were white and slightly depressed. Dispersed over the rest of the scalp, which was covered by a strong coat of hair, were a number of small red papules covered with a brown scab, but there were no scutula. On December 9th the patient was put under ether and, after disinfecting the fingers thoroughly, both nails were extracted by means of Post's nail forceps. The evulsion of the nails was accomplished without difficulty. The fungus was found in the scrapings taken from the under surface of the extracted nail plates, which seems to be the place of predilection for the settlement of the achorion schoenleinii. There were no spores, but only mycelia. After the operation the finger was covered with iodoform gauze and protected by

a cap formed of small slips of adhesive plaster, which finally was painted with flexible collodion. In this case, as in most of the other cases reported in literature, the scalp showed signs which confirmed the diagnosis. From a microscopical standpoint alone the diagnosis is quite difficult, because it is difficult to obtain scrapings which contain the mycelia. In a case published by Dr. Leviseur in 1898 in the *Journal of Cutaneous and Genito-Urinary Diseases,* conditions were very similar to the present one. The treatment differed only in this, that the nail plates were allowed to grow for some time without cutting and formed a hollow shell from their free border to the lunula. It was then easy to pull them out under local anesthesia with ethyl chloride. Dr. Leviseur believes that the removal of the nail is the best method of curing this obstinate affection after it has once made some inroad and antiparasitic salves and lotions have shown their inability to do good. The new nail developing from the matrix pushes forward the diseased tissue, and all that is necessary to do is to keep the fingers bandaged with an antiseptic salve.

Ordinary Remedies.—In the discussion Dr. Lusk said that while favus in any part of the body is often obstinate to treatment the faithful application of a reasonably-strong solution of caustic potash or of a 10-per-cent. solution of pyrogallic acid in alcohol usually affects a cure. Patience on the part of the physician and sufferer is necessary.

Dr. Whitehouse said that until some recent experience he would have agreed with Dr. Leviseur as to the advisability of removing the nail in these cases. In a recent case, however, he had employed Dr. Johnson's remedy, namely, saturated solution of potassium iodide and tincture of iodine, in patients in whom all other kinds of treatment had failed and the favus fungus completely disappeared and the tissues had resumed a healthy look in six weeks. After three months there was a new smooth nail. This remedy, though rather dark-colored itself, does not produce a dark discoloration of the fingers; in fact, it is scarcely disfiguring at all. This forms a very easy method of treating what is usually an extremely obstinate affection. Dr. Whitehouse thinks that this remedy should be tried before employing the more radical method of avulsion of the nails.

Inconveniences of Other Remedies.—Dr. Goldenberg said that the usual remedies recommended for the treatment of favus are eminently unsatisfactory. Even when most successful they must be employed for long periods and require the most careful attention. Caustic potash and pyrogallic acid have not proved as effective in his hands as they seem to have done in those of others. With regard to caustic potash, Dr. Goldenberg has a word of warning to others. If the nail matrix is exposed, as is not infrequently the case in these patients, applications of strong solution of caustic potash are apt to give rise to severe and lasting pain. For this pain ordinary anodyne remedies, locally applied, fail to give relief. The patients complain very bitterly.

Avulsion of Nails.—In closing the discussion Dr. Leviseur said that the ordinary remedial treatment suggested for favus of the nail had proved so unsatisfactory in his experience that he considered it justifiable to remove the nails, for this seemed to be the only way by which prompt and sure cure could be obtained. In another case under Dr. Leviseur's care some time ago, the patient had been treated by all manner of methods. The old nails were loose and were easily removed and then the new nails, in their growth, proceeded to do away with the products of the old inflammatory process and gave, notwithstanding the severity of the old process, an excellent result.

Cystoscope for Double Ureteral Catheterization.—Dr. Bierhoff presented a modification of the ordinary cystoscope that is meant to facilitate the introduction of catheters into both ureters at the same time, so as to permit of the simultaneous collection and comparison of the urine passed from each kidney. The simultaneous collection of the urine is necessary, especially in such tests as those with methylene blue or phloridzin. With the old form of cystoscope it was extremely difficult to insert the second catheter when one was already in place, and then the removal of the cystoscope often led to the removal of at least one of the catheters from the ureteral opening, because the instrument became entangled in the catheters. The distinguishing features of the new cystoscope are the existence of two complete tunnels for the ureteral catheter and an arrangement by which, after the insertion of the catheters, the cystoscopic portion of the instrument may be turned completely around so as to permit of its removal without the beak interfering with the catheters. This latter provision prevents entanglement and the premature removal of the catheters. Another advantage of the instrument is that the presence of the two tubes enables it to be used as a double-current irrigating instrument. If the fluid in the bladder becomes turbid it may be removed and a fresh solution readily introduced. The use of stopcocks at the external end of the catheter tubes enables the instrument to be used also as a single catheterizing instrument. One of the other advantages of the instrument is that it is entirely made in this country, that it is equal to the best German instrument and that it can be repaired, or parts of it can be replaced without delay and difficulty. While the cystoscopic portions of the instrument, as in all other cystoscopes, can not be sterilized by boiling, but must be cleansed by antiseptics, all the catherizing portion of the instrument can be boiled.

Ureteral Catherization.—Dr. Bierhoff answered certain questions in reference to the employment of ureteral catheterization in general. With regard to direct and indirect illumination, he said that the straight tube which permits of direct illumination may be readily employed in the phantom or where there is a perfectly level vesical floor. In prostatic cases, however, the use of the straight instrument is impossible. Whenever any distortion exists in the bladder, it is usually in the trigone. The straight tube can be always available only when it will be possible to look around a corner by direct vision. If the operator knows his instrument, if he has sufficient illumination, if he knows that the cystoscope will pass, and if clear fluid is in the bladder, there should be no difficulty for an expert to pass a ureteral catheter. The bladder must be sufficiently distended with fluid and the light must be as nearly white as can be obtained. Under favorable conditions Dr. Bierhoff has never failed to pass catheters into the ureters.

BOOK REVIEWS.

PEDIATRICS. THE HYGIENIC AND MEDICAL TREATMENT OF CHILDREN. By THOMAS MORGAN ROTCH, M.D., Professor of the Diseases of Children, Harvard University. Third Edition. J. B. Lippincott Company, Philadelphia and London.

THIS edition shows Dr. Rotch's book in an almost entirely new form, having been most thoroughly and systematically revised. For many years this treatise has been one of the best classics in the English language, dealing with the development and care of children in sickness and in health. Dr. Rotch has not limited himself to the study of disease processes alone; he has given almost as much space to the hygienic care

of the child during health as to the study of diseased conditions.

The chapters on infant feeding are especially valuable, although we confess that it is somewhat unreasonable to impose on the practitioner the long algebraic formulæ which are here taken from Westcott. There are enough simple methods described, however, whereby the home modification of milk may be easily and satisfactorily accomplished. We believe that the medical profession and the lay public alike are to be congratulated that such an excellent work has been so thoroughly brought up to date.

First Aid to the Injured and Sick. By F. J. Warwick, B.A., M.B. Cantab., Associate of King's College, London, and A. C. Tunstall, M.D., F.R.C.S. Ed., Surgeon-Captain Commanding the East London Volunteer Brigade Bearer Company. W. B. Saunders & Co., Philadelphia and London.

This book seems to be a very valuable compendium of practical suggestions. The illustrations show especially the use of the triangular bandage and of unusual forms of bandages of special form—the square bandage, the four-tailed and the many-tailed bandage. The chapter on the immediate treatment of sprains and fractures is very practical because of its suggestiveness as to the use of material likely to be near at hand in case of accident. As a whole the little book is one of the best of its kind. It contains in very convenient form chapters on the transportation of the sick and injured, on poisons and their immediate treatment and the immediate treatment of insensibility and fits.

Text-Book of Nervous Diseases. Being a Compendium for the Use of Students and Practitioners of Medicine. By Charles L. Dana, A.M., M.D., Professor of Nervous Diseases in Cornell University Medical College. Fifth Edition. William Wood & Company, New York.

Dr. Dana's text-book is too well known to need special words of commendation. The fifth edition of the work has been reached in less than ten years. As the subject of nervous diseases is of less general interest to physicians, this fact is of itself sufficient to demonstrate the merits of the book by its popularity among the profession.

The present edition does not differ very materially from the fourth. There are some minor changes in the microscopic anatomy of the nervous system and a short chapter upon the diagnosis of the diseases of the cauda equina. The chapter on myelitis has been rewritten and the book is now thoroughly up to date in this progressive subject. It is an index of present tendencies in neurology that the author has seen fit to add a chapter on general paresis, since, as he says, it is a disorder which belongs fully as much to neurology as to psychiatry. Notwithstanding the additions, careful elision and compression have kept the work from being larger than before, so that it remains a very handy reference-book in its increasingly important subject and at the same time one of the best text-books of the kind in any language.

Greek Thinkers. A History of Ancient Philosophy. By Theodore Gomperz, Professor at the University of Vienna and Member of the Imperial Academy. Translated by Laurie Magnus, M.A., Magdalen College, Oxford. Charles Scribner's Sons, New York.

No philosopher who was unacquainted with modern science could have traced as Professor Gomperz has done the history of all knowledge back to the first deep impulses that stirred the philosophers of Greece to search for facts and truths. In each section the author asks: "What elements of modern science were implicitly present in the doctrines of the earliest philosophers who were seeking for knowledge?" He showed that Pythagorus discovered that sound is subject to a numerical law; that the idea of evolution was foreshadowed in the assumption that the world-process is a continuous one, and that Empedocles anticipated Darwin's doctrine of the survival of the fittest in the struggle for existence. He traces back to their sources the sciences of astronomy, chemistry, physics and botany; but what interests us most is his chapter on Greek physicians.

"The threads that bind antiquity to modern times lie open to view," and it is with his index finger on these threads that the author leads us back through the maze of tradition, mysticism and sophistry to the old and famous center of medicine in the island of Cos, where was born Hippocrates the Great, who was "recognized by all antiquity as the type of the perfect physician." With the art of the dramatist he vivifies the dead names of the physicians of the famous school of Cos, and pictures their keen methods of observation, their faulty generalizations, their conflicts with superstition.

There is in this summary the same perception of essentials and clear expression of relations that characterize the whole book: "The pioneer virtues which distinguished the Coic masters from their opponents were a self-abnegation, and a timely renunciation of ambitions, fascinating enough, and even exalted in themselves, but at that era and long afterward out of reach, and these virtues entitle them to our ungrudging admiration at this day. We recognize their supreme merit in having developed, with tireless powers of observation and extraordinary faculties of clear sight and strong sense, those branches of the art of healing, which were capable of extension without digging their foundations more deeply. Above all we may specify their contributions to symptomatology, which, by their endless supply of nice distinctions and acute observations, are a source of pleasure and instruction to modern students of that branch of learning."

The dawn of the allied sciences illumines each the other, and the physician who feels that he is becoming narrowed by the restrictions and exactions of his profession will find stimulus and breadth in meeting in the pages of this masterly work the very incarnation of the Greek Thinkers.

The Protozoa. By Gary N. Calkins, Ph.D., Instructor in Zoology, Columbia University. Columbia University Biological Series. VI. The Macmillan Company: New York.

The medical man of the present day is as well posted on microscopical plants, it might be said more so, than on the flowers of the field, and, if the recent developments of animal parasitology are to continue at the present rate, it will be incumbent on the student of the future to know his microscopical animals as well as those of more mighty stature.

This work of Dr. Calkins will prove a very important one to the student of the lowest forms of animal life, the protozoa, and is to be cordially commended to the medical man with tastes, biological and microscopical. It is strongest on the details of morphology and of cytology, less valuable from the taxonomic standpoint and of no value to the superficial student who wishes only to find the name of a species.

Considerable space is given to the discussion of the parasites of malaria and similar parasites, and this aspect of the work is very satisfactorily handled. It is to be remembered, however, that the work is not written particularly for the student of medicine, but for the

zoologist, nevertheless the practitioner who is interested in the primary problems of animal physiology can find much in it that will amply repay for the reading.

MANUAL OF THE DISEASES OF THE EYE. For Students and General Practitioners. By CHARLES H. MAY, M.D., Instructor, Eye Department, in the College of Physicians and Surgeons, Medical Department of Columbia University. Second Edition. William Wood & Company, New York.

THIS work, the first edition of which found such a favorable reception, has been thoroughly revised in the second edition and improved by the additions and alterations. The chapter on ocular therapeutics has received special attention. Some colored plates have been added. One showing changes in the media as seen by oblique illumination and by the ophthalmoscope at a distance is especially valuable. Another plate, illustrating the various micro-organisms found in conjunctival, corneal and lacrimal diseases, is useful on account of the greater interest now taken in the bacteriology of the eye. We have the same reasons for commending this book now as when we reviewed the first edition.

A LABORATORY HAND-BOOK OF URINE ANALYSIS AND PHYSIOLOGICAL CHEMISTRY. By CHARLES G. L. WOLF B.H., M.D., Instructor in Physiological Chemistry, Cornell University Medical College, New York. Philadelphia and London: W. B. Saunders & Company.

THIS small manual differs in no essential manner from many others devoted to similar subjects, save that we do not consider it as good as some others which have been published recently. The part devoted to physiological chemistry is very meager. The urinary examination features, however, are very excellent and we believe the work accurate and reliable. It bears the impress of much personal experience. Some tables of diagnosis at the end of the work will be found very helpful, even if more didactic than modern medicine will permit.

THE PRACTICE OF OBSTETRICS. By American Authors. Edited by CHARLES JEWETT, M.D., Professor of Obstetrics and Gynecology in the Long Island College Hospital, New York. Second Edition. Lea Brothers & Co., New York and Philadelphia.

UP TO DATE this is probably one of the most praiseworthy attempts at a tangible text-book on obstetrics that have been published in the last decade in the English language. Dr. Jewett has endeavored to collect the best ideas of American workers in the various departments of midwifery. The arrangement of the various sections of the book is most excellent and a decided improvement over the time-honored custom.

We regret that Cæsarian section is really neglected in the comparison with the chapter upon symphysiotomy to which entirely too much space is devoted. This procedure is nowadays scarcely in vogue, but is more or less warmly advocated in this publication.

The bacteriology and pathology of obstetrics is most ably and carefully set forth whenever any occasion arises for their explanations.

Unfortunately, it is impossible to get together such work and eliminate the personal element of the various contributors. And this is none the less evident in this case. However, we are indebted to Dr. Jewett for the small amount of this in his collaboration. The text is most interesting and the illustrations are clear and sufficient. The whole book is tastefully and neatly designed.

The following is a list of contributors: Charles Jewett, Elias Bartley, A. T. Bristow, A. H. Buckmaster, J. C. Cameron, H. D. Chapin, M. A. Crockett, R. L. Dickinson, J. C. Edgar, A. McL. Hamilton, F. Henrotin, W. P. Manton, C. D. Palmer, Jno. O. Polak, Hunter Robb, J. M. Van Cott, H. N. Vineberg, J. C. Webster, and J. Whitridge Williams.

A LABORATORY COURSE IN BACTERIOLOGY. For the Use of Medical, Agricultural and Industrial Students. By FREDERIC P. GORHAM, A.M., Associate Professor of Biology, Brown University. W. B. Saunders & Company, Philadelphia and London.

FOR the exact purposes for which it is meant this is a splendid little volume. Within a very small compass it discusses the fundamental principles of the life-history, growth-characters, and general features of bacteria. The modes of cultivation, the technic of staining and general classroom-laboratory mode of dealing with such problems is very clearly and succinctly set forth.

While this volume will be of secondary use to an advanced student, for a beginner, particularly in agricultural colleges, colleges of pharmacy, and in the smaller medical colleges, it will be found of good service and it is to be recommended cordially.

ATLAS AND EPITOME OF SPECIAL PATHOLOGIC HISTOLOGY. By Dr. HERMANN DURCK, Assistant in the Pathologic Institute, Munich. Edited by LUDVIG HEKTOEN, M.D., Professor of Pathology in Rush Medical College, Chicago. W. B. Saunders & Company, Philadelphia and London.

THIS is the second volume of the author's "Special Pathologic Histology" and includes the lesions found in the liver, the urinary organs, the sexual organs, the nervous system, the skin, the muscles, and the bones, thus completing the field of special pathology. The author purposes to issue a third volume on general histology.

We have already spoken of the high class character of Dr. Dürck's first volume. His second contribution sustains the reputation of the first and cannot fail to be of great service, not only to the student of medicine, but to the teacher. The illustrations are remarkably well done, the colored plates being very clear and comprehensive. For a work of the size, and for the price, it seems impossible that anything better could be produced.

THE ROENTGEN RAYS IN MEDICINE AND SURGERY AS AN AID TO DIAGNOSIS AND AS A THERAPEUTIC AGENT. Designed for the Use of Practitioners and Students. By FRANCIS H. WILLIAMS, M.D. (Harv.), Visiting Physician at the Boston City Hospital. The Macmillan Company, New York.

DR. WILLIAMS is already known as one of the best authorities in this country on the use of the Roentgen rays in medical and surgical diagnosis and in the other applications of this new electrical agent. The present volume firmly establishes his reputation as an expert in the matter of Roentgen-ray knowledge and, at the same time, serves to show how much this recent discovery means not only for diagnosis, but for therapeutics.

As might well be expected, the chapters on the use of the X-rays as a means of diagnosis in pulmonary tuberculosis are complete and very informing. The book is not loaded down with a series of illustrations without peculiar significance. Illustrations are introduced always with a definite purpose and serve to bring out very clearly the important points that Dr. Williams wishes to emphasize.

The chapters on the applications of the X-rays to the

diagnosis of fractures and dislocations, as well as the recognition of deformities and congenital malformation, contain a very thorough discussion of all the technical points connected with these subjects. The chapter on dental surgery shows how significant the Roentgen skiagrams may be in the recognition of unerupted teeth, of alveolar abscess, of fractures of roots and of fluid in the antrum. All of these details were practically beyond the positive diagnostic knowledge of the dental surgeon before the days of Roentgen's discovery.

The therapeutic uses of the X-rays and especially their action on bacteria in the tissues receive very thorough consideration. The favorable employment of the X-rays for the cure of lupus makes an especially interesting part of this chapter. The use of this electrical agent also in the treatment of external forms of cancer receives an up-to-date discussion that will prove especially informing to the general practitioner who is interested in knowing how far the meager, but very promising results that occasionally are reported are justified by the actual experience of a conservative and expert observer.

A Civilian War Hospital. Being an Account of the Work of the Portland Hospital, and of Experience of Wounds and Sickness in South Africa, 1900. By the Professional Staff. Anthony A. Bowlby, Senior Surgeon, Howard H. Tooth, Cuthbert Wallace, John E. Calverley and Senior Major Kilkelly. Longmans, Green & Co., New York.

The preface of this very interesting work tells us that the "Portland Hospital" was the first of the civilian hospitals to be equipped and sent to South Africa after the opening of the Boer war in October, 1899.

The character of the work is largely descriptive of the work of the hospital and of its equipment, and is a complete and very agreeable contribution to the broader aspects of modern warfare considered from its medical side, the economics of the running of the hospital being an especially practical and illuminating chapter.

As a contribution to medical and surgical science, the work is worthy of commendation. The joint authors have confined their attention to a few salient features, and wisely, we believe, to those of the greatest practical importance. Thus, the subjects of typhoid fever, the various forms of dysentery, diseases due to exposure, sunstroke and mental disturbances, are taken up in a serious and eminently satisfactory manner.

The surgical discussions take up the varying features depending on gunshot wounds and contribute much important data to the understanding of this absorbing topic. A series of appendices are very ingenious and cast many side lights on the economic features of such a project. To the military surgeon, engineer or hygienist such a work comes as a boon and to the outside profession as an opportunity.

A Text-Book of Physiological Chemistry. For Students of Medicine and Physicians. By Charles E. Simon, M.D., of Baltimore, Md. Lea Brothers & Co., New York and Philadelphia.

From the first glance of this work one is struck with the great amount of information that is contained in this work of really small compass; a further study shows that the author has made an extremely careful choice of the facts of physiological chemical science and has had the rarest of powers in being able to tell the facts in a way that makes them vivid and real.

Modern-day therapeutics, not to mention physiology, is so essentially bound up with chemical problems that the physician of the present day perforce needs to know all that is found in a work of this kind, and we know of none better and few as good for the purpose. We can heartily recommend it as authentic, concise, not too theoretical and yet judicious in its handling of mooted points.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

First Aid to the Injured and Sick. By Drs. F. J. Warwick and A. C. Tunstall. 12mo, 232 pages. Illustrated. W. B. Saunders & Company, Philadelphia and London.

The Principles of Pathological Histology. By Drs. Harvey Gaylord and Ludwig Aschoff. Quarto, 359 pages. Illustrated. Lea Brothers & Co., New York and Philadelphia.

The Surgical and Medical History of the Naval War between Japan and China during 1894-1895. By Baron Saneyoshi and S. Suzutsi. 8vo, 544 pages. Illustrated. Tokio.

Die Nervöse Schlaflosigkeit ihre Ursachen und ihre Behandlung. By Dr. Max Heim. 8vo, 59 pages. Friedrich Cohen, Bonn.

Essentials of Physiology. By Sidney Budgett. 8vo, 233 pages. Illustrated. W. B. Saunders & Company, Philadelphia and London.

Memoirs and Letters of Sir James Paget. Edited by Stephen Paget, one of his sons. 8vo, 438 pages. Illustrated. Longmans, Green & Co., New York, London and Bombay.

The Mental Functions of the Brain. By Dr. Bernard Hollander. 8vo, 507 pages. Illustrated. G. P. Putnam's Sons, New York and London.

Practical Medicine. By Dr. F. Mortimer Lawrence. 8vo, 521 pages. Illustrated. Boericke & Tafel, Philadelphia.

A Practical Guide to the Administration of Anæsthetics. Dr. R. J. Probyn-Williams. 12mo, 211 pages. Illustrated. Longman, Green & Co., New York, London and Bombay.

Phototherapy. By Dr. Niels R. Finsen. Translated from German Edition by Dr. James H. Seguira. 8vo, 79 pages. Illustrated. Edwin Arnold, London.

An Experimental and Clinical Research into Certain Problems Relating to Surgical Operations. By Dr. G. W. Crile. 8vo, 200 pages. Illustrated. J. B. Lippincott Company, Philadelphia.

The Baby. His Care and Training. By Marianna Wheeler. 12mo, 188 pages. Illustrated. Harper & Brothers, New York and London.

Transactions of the Twenty-third Annual Meeting of the American Laryngological Association, Held at New Haven, Conn., 1901. Rooney & Otten Printing Co., New York.

The Four Epochs of Woman's Life. By Dr. Anna M. Gailbraith. 8vo, 200 pages. W. B. Saunders & Company, Philadelphia and London.

Gynecological Pathology. By Dr. Carl Abel. Edited by Dr. S. W. Bandler. 8vo, 237 pages. Illustrated. William Wood & Company, New York.

Transactions of the Association of American Physicians. Sixteenth Session. Vol. XVI.

Venereal Diseases. A Manual for Students and Practitioners. By Dr. James R. Hayden. Third Edition. 8vo, 301 pages. Illustrated. Lea Brothers & Co., New York and Philadelphia.

A Manual of Clinical Laboratory Methods. By Dr. J. B. Nichols. 8vo, 301 pages. Illustrated. William Wood and Company, New York.

ORIGINAL ARTICLES.

THE CAUSATION OF MULTIPLE NEURITIS.

BY M. ALLEN STARR, M.D., LL.D.,

OF NEW YORK;

PROFESSOR OF NERVOUS DISEASES, COLLEGE OF PHYSICIANS AND SURGEONS; MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY.

THE diagnosis of multiple neuritis no longer presents any difficulty, as the symptoms of the disease are now well known, and their various combinations, presenting paralytic, ataxic, neuralgic, and vasomotor types of the affection, according to the predominance of one set of symptoms over others, are everywhere recognized.

But as the clinical study of the disease has become more exact and complete it has become evident that a very large number of different causes may act to produce it. And in order to emphasize this fact it appears to be time to classify these causes more accurately, and to call attention to some which are unusual. This is not the first attempt at such a classification, for in 1887 in the Middleton Goldsmith Lectures cases were divided into toxic, infectious, epidemic, and due to uncertain causes. Gowers in the second edition of his text-book on Diseases of the Nervous System, 1892, classified the cases into (1) toxic, (2) toxemic, (3) endemic, (4) rheumatic, and (5) cachetic and senile, and Remak, in Nothnagel's Specielle Pathologie und Therapie, Vol. XI., has adopted a somewhat similar classification. If these classes be taken as a provisional basis and the various causes which are known be studied, we may finally reach a fairly satisfactory series of categories to which the cases may be assigned:

I. Toxic cases due to the action of a poison derived from without the body. (1) Metallic: arsenic, lead, mercury, copper, phosphorus, and silver. (2) Non-metallic: alcohol, carbonic oxide gas, bisulphide of carbon, sulphonal and trional, the coal-tar products, and nitrobenzol.

1. In discussing these toxic agents I wish to call your attention to some which have not been commonly recognized, or rather to some unexpected means by which they may get into the system.

a. Arsenic.—It has long been known that arsenic can produce neuritis. Not infrequently persons who fail in attempts at suicide by taking arsenic suffer for a long time from the neuritis which develops after the attempt. Occasionally children who are being treated for chorea by arsenic show unusual susceptibility to the drug and develop neuritis. Neuritis may also be due to the inhalation of arsenic which is given off from wall-papers and furniture-covering, or from artificial flowers containing arsenical dye-stuffs. One of the most severe cases I have seen developed in a woman who, in order to avoid miscarriage, was confined to her bed during the first six months of pregnancy. To make her room attractive a new green paper and green cretonne furniture were put in which were subsequently found to be loaded with arsenic. In the third month her continued vomiting which had been ascribed to the pregnancy was followed by a rapidly-developing, painful paralysis in legs and forearms, the thighs and arms and body being exempt. A general brown pigmentation of the skin also appeared which was the symptom suggestive of the arsenical cause of her neuritis—a suggestion confirmed by the discovery of arsenic in the urine. As she had never left her room and had not been given during her illness any arsenic medicinally, there could be no doubt as to the fact that the arsenic had been inhaled from particles in the air.

It is not to be forgotten that many toilet powders contain arsenic and they may thus easily cause neuritis. But the most interesting fact regarding the possibility of arsenical poisoning was elicited about two years ago in the epidemic of arsenical poisoning from the use of beer in England.[1] It was noticed in November and December, 1899, in Manchester, Salford, Liverpool and the adjacent towns that a very unusual number of cases of neuritis were applying for relief to the hospitals. While these cases were at first regarded as alcoholic, the peculiar pigmentation of the skin and the numerous trophic symptoms, such as changes in the nails, which became ridged, thick, and brittle; erythema, acne, eczematous, papillary and herpetic eruptions, and thickening of the skin over the knuckles and on the palms and soles, with desquamation, soon suggested arsenic as a cause. Investigation revealed the fact that all the patients had drank freely of beer from a few breweries, and certain of these beers were found to contain arsenic in the proportion of from 0.28 to 0.14 of a grain of arsenious acid to the gallon. Thus, a man drinking four quarts a day would get the equivalent of 30 minims of liquor arsenicalis. Chemical examination proved that the arsenic was derived from the glucose or invert sugar used in brewing, and not from any other of the constituents of the beer. The glucose contained four parts of arsenic to 10,000. Glucose, as is well known, is derived from corn or other kinds of starch by the action of sulphuric acid. Sulphuric acid is now manufactured from arsenical pyrites, and such acid is rarely free from arsenic. Hence the source of the arsenic in the beer. Prompt action by the legal authorities in England caused the destruction of thousands of gallons of this arsenical beer, and the epidemic ceased. The glu-

[1] British Medical Journal, Dec., 1899, and Oct., 1901.

cose manufacturers were alarmed at the danger and the American Glucose Company stopped entirely the use of sulphuric acid in the preparation of glucose, to avoid the danger. But the fact remains that unless care is taken in the manufacture of glucose and its use in beer such a neuritis may develop anywhere and at any time from similar cause. Last winter I saw at St. Vincent's Hospital two cases of supposedly alcoholic neuritis from beer-drinking (in one of which a bilateral facial paralysis occurred as an interesting symptom) attended by the characteristic arsenical pigmentation; and I am convinced that once this causation is suspected many cases will be observed. It may be well to state that the pigmentation is a dark brown in color which makes one think at first that the patient is an octoroon or a mulatto, but later may suggest Addison's disease. The pigment appears first on those parts of the body normally pigmented, the axillæ and groins and the nipples. It soon appears on the eyelids, on the abdomen and thorax and finally on the extensor surfaces of the arms and legs. The pigment is diffuse, but here and there little islets of normal skin give a mottled appearance to the surface. The mucous membranes are never pigmented, hence the condition need not be mistaken for Addison's disease. I saw last winter with Dr. A. H. Smith at the Presbyterian Hospital a man suffering from a most extreme type of neuritis, attended by the rare complication of paralysis of the diaphragm, in whom this pigmentation suggested arsenic as the cause of the disease. The urine was found to contain arsenic. This patient was attacked by paralysis in the mountains of Brazil, where he was working as an engineer. He had suffered from severe malaria and, in the absence of other causes, it was supposed that his malaria was the cause of the neuritis. He had drank a bottle of English beer daily for some months. He had taken large doses of quinine and some arsenic. It is still a matter of doubt which of these three causes produced his neuritis, for as we shall soon see the disease often develops after malarial fevers, and it is not impossible that large doses of quinine long continued may cause general neuritis, as it is known to cause atrophy of the acoustic nerve.

Sulphuric acid is used in so many of the arts and manufactures that it would be well for those who practise among such workers to be on the lookout for chronic arsenical poisoning. Arsenic is so commonly found in copper, and copper is now being used so widely in electrical construction, that it is not strange that workers in copper are often the subjects of arsenical poisoning. The presence of $^1/_{200}$ of 1 per cent. of arsenic in copper renders the copper useless for many electric purposes. The arsenic is extracted by heat, going off in fumes. In factories where these fumes have been conducted to a height of 250 feet by tall chimneys, the workmen about the copper works constantly present arsenic poisoning, the particles dropping from the gases, being scattered all over the adjacent buildings, getting into the air and so being inhaled. I am told that these workmen are often attacked by paralysis, from which they gradually recover. It seems likely that this paralysis is really an arsenical multiple neuritis.

b. Lead.—The frequency of lead-palsy, which is always a form of multiple neuritis, and the widespread knowledge of its origin among painters, plumbers, typesetters and workers in lead toys makes it unnecessary to devote time to its consideration. It may not be so generally known that laborers who produce china, earthenware glazes, and fritted glass are equally liable to lead-poisoning. In the midland counties of England, in Limoges, France, and in Dresden and Prague, neuritis from this cause among these workmen is very common.[1] It would be well for those who practise in Trenton, N. J., Cincinnati, and Denver to watch for such cases in the factories where similar products are turned out.[2] It seems to be well admitted that persons addicted to alcohol are more liable to lead neuritis than are the temperate. The possibility of a contamination of water by lead from lead pipes is never to be forgotten. Old pipes become lined with soluble salts of lead which may render the water which is allowed to stand in the pipes quite poisonous. Thus, cases are reported of servants who have drank the water first drawn from a faucet in the morning, without letting it run a while, and have thus been poisoned. It is interesting to know that horses are subject to lead-palsy.

c. Copper.—Allusion has been made to the occurrence of arsenical neuritis in those who are busied in extracting arsenic from copper. But copper itself may be the cause of neuritis. Suckling has called attention to a form of multiple neuritis developing in brass-workers in England, and in this country Walton and Carter have confirmed his observation. This fact requires emphasis for such cases will probably be found if looked for in those localities where copper is burned or worked.

d. Phosphorus.—Henschen has seen cases of both mild and severe types of multiple neuritis following poisoning by phosphorus. It is not unlikely that this may be the origin of many nervous symptoms to which those who work in match factories are peculiarly liable. But further investigation is needed to establish the existence of neuritis.

e. Mercury.—The various types of paralysis attended by tremor due to inhalation of fumes of mercury are now rarely seen, though formerly when looking-glass was manufactured by the

[1] In a report of the effects of lead upon lead-workers in the Staffordshire potteries, Dr. Shufflebotham of Newcastle-on-Tyne found that but few workmen were affected (Lancet, Oct. 28, 1901); but in the Inspectors' report (Lancet, Oct. 12,) it appears that, of 8,637 individuals employed in earthenware and china industries in 1900, 323 suffered from lead-poisoning, i.e., about 4 per cent. the greater part of whom were poisoned by inhaling dust laden with lead.

[2] It is interesting to know that the lead in the glaze which lines so many agate pots and dishes used in cooking may be dissolved out by the acids and fats in food and thus may cause lead-poisoning. Some such cases have recently been reported in England.

older methods they were very common.[1] The lesion in such cases was a multiple neuritis. I have seen several patients suffering in this manner. Fortunately, the newer method of precipitating the mercury on the glass by electrolysis does not expose the workmen to the fumes. I have never seen the medicinal use of mercury cause a multiple neuritis.

f. Silver.—The only case of neuritis ascribed to silver-poisoning is recorded by Gowers. His patient had taken silver pills for years for cancer from which he subsequently died; he had the blue discoloration caused only by silver and the silver was the only assignable cause for an undoubted case of paralysis of the type of lead-palsy.

2. Poisoning by non-metallic substances is much more common than by those already considered.

a. Alcohol.—The vast majority of cases of multiple neuritis seen in private and in hospital practice are traceable to alcoholic excesses. It was formerly supposed that whisky, brandy, gin and rum and the liqueurs were the only forms of drink strong enough in alcohol to cause neuritis. They are certainly the usual cause of the disease. But further observation has shown that in some persons susceptible to alcohol, red and white wine, or even ale and beer may produce the disease. It seems that this susceptibility may be manifest not as a mental one merely, but also as an inherent weakness in the nerves. We recognize that undue elation, talkativeness, egotism, or combativeness may appear in certain persons under small amounts of alcohol which fail to affect other individuals at all. Is it not probable that persons may show similar variability of effect of the drug in the nerves as well as in the brain-cells? I have been surprised to find how free some are from alcoholic nervous symptoms after long and steady and copious habitual drinking. I have also been surprised to find what small amounts of liquor or even beer will in others cause serious neuritis. I have seen a case of severe multiple neuritis in a child of three years whose mother gave her a "sup of beer" once a day at dinner. It is never to be forgotten that many substances contain alcohol and if taken may cause neuritis which might not be suspected. One undoubted case of alcoholic neuritis in a man who prided himself on his temperance record was traced to a patent remedy which he had long taken almost daily for so-called dyspepsia. He had found it necessary gradually to increase the dose and he was taking about eight ounces daily of thsi nostrum. Analysis showed it to contain 70 per cent. of pure alcohol. In the case of a woman whose symptoms were typical, and whose indignation at my questions regarding concealed drinking was shared by all her family, careful observation elicited the fact that she was sipping cologne, and consumed about six ounces a day. It is to be remembered that the inhalation of alcohol is more rapid in its effects and equally deleterious as its absorption by the stomach Those who work in drug factories in all manufactures where alcohol is used and where its fumes may be inhaled are liable to neuritis. For it is the constant absorption of small amounts, keeping the system continually under the influence, which is more likely to cause neuritis than are occasional large doses.

Males are actually the victims more often than females. Thus, of 250 cases which I have seen or collected, 89 only were in female. But when the far greater prevalence of drinking among men is considered it is evident that the disease is relatively far more frequent among women. It is likely that a sedentary habit predisposes to it and hence active workers, male or female, though taking an equally large amount of liquor as does the luxurious lazy drinker, escape. I think that neuritis is more commonly seen among the higher classes and in those whose nervous organization is more highly developed than in the lower or coarser types.

I would also call attention to the existence of a chronic alcoholic multiple neuritis in mild drinkers, characterized by numb extremities, occasional neuralgia, a general enfeeblement of the muscles, and edema of the feet, which may persist for years and never go on to actual paralysis or ataxia. These cases have not been recognized or mentioned in the books.

b. Coal Gas.—When inhaled coal gas may cause a severe type of sensory neuritis. Two of the most obstinate cases I have seen were in patients who barely survived the experience of sleeping in rooms where the gas was turned on. It is not generally known that natural gas may produce the same effect. In the case of a man from Peru, Ind., three successive attacks of the disease were definitely traced in the absence of all other causes to his exposure to inhalation of natural gas both in his house and in his office. And I am told that neuritis has increased in Pittsburg during the last few years since natural gas has been extensively used as a fuel. There is little effort to save this gas and complete combustion is not always obtained. Hence it gets into the air of badly-ventilated rooms and is inhaled. I have seen several cases from cities in the Middle States, where natural gas is freely used, which have been there considered neurasthenic but which were really cases of chronic multiple neuritis, and possibly due to this cause.

c. Sulphide of Carbon.—This substance is present in rubber and multiple neuritis developing in workmen in rubber factories has been traced directly to it as a cause. The fumes from heated rubber or the dust containing particles of rubber are inhaled or get into the mouth and nose and are then swallowed, causing a chronic

[1] In the report of the Chief Inspector of Factories and Workshops in Great Britain for 1900 (Lancet, Sept. 28, Oct. 12 and 28, 1901) it is stated that few cases of mercurial poisoning were discovered. These were chiefly among manufacturing chemists who produced calomel, corrosive sublimate and red oxide, all of which are made by volatilizing the metal. Makers of thermometers and of electrical meters were also affected. In the making of hats nitrate of mercury is used for the preparation of the fur and workers here suffered.

poisoning. The symptoms are at first those of general anemia and disturbance of digestion, headache, inability to fix the attention or to remember, and many functional nervous symptoms suggestive of hysteria follow. Finally symptoms of multiple neuritis either of the paralytic or of the ataxic types develop, causing long and serious illness. Such cases have been rather widely observed abroad, but have not been recorded in this country. They are most completely described by Laudenheimer.[1] Inasmuch as our rubber industry is becoming very extensive, since the introduction of rubber tires, it may be worth while for those who come in contact with employees in the rubber factories to be on the lookout for these cases.

d. The Coal-Tar Products.—Antipyrin, acetanilid, sulphonal and trional, chloretone, and other coal-tar products are so widely used as medicinal agents that much interest has been awakened by recent statements that they are capable of causing multiple neuritis. I think we have all seen nervous symptoms caused by overdosage of these drugs. The cardiac weakness and cyanosis are probably due to paralysis of the vagus nerve. The marked relief of pain is often attended by numbness of the extremities and feelings of weakness. It has been affirmed that the long-continued use of antipyrin, acetanilid and phenacetin has been the cause of multiple neuritis. I have not seen such cases; but Remak, who has reported one case, is a most accurate observer. I have seen a case of acute sulphonal-poisoning, in which the patient took 120 grains of the drug within three hours. She slept two days, being during this time very cyanotic, with weak, rapid pulse, 120, and slow, shallow respiration. For three weeks after this she suffered from paresthesia of the extremities and from weakness and ataxia of the hands and legs, with extreme tenderness along the distal parts of the nerves, symptoms easily referable to a mild neuritis, and not unlike those seen after alcoholic or coal-gas poisoning. Dr. Stuart Hart has recently reported[2] a case of trional habit followed by multiple neuritis. As I saw this patient, I can confirm his diagnosis; and, in view of the probable exclusion of other causes and of the fact that he has been able to find other cases similar in kind in the literature, I think we must admit that trional if long taken in large dose may produce neuritis.

Ross called attention to cases of multiple neuritis occurring among miners who use roburite (dinitrobenzol) and also to cases occurring in factory workers who use the anilin dyes and oils. We all know of the relative action of methylene blue upon the nerves in the laboratory and of the recent attempts—not very successful—to introduce this dye into the Pharmacopœia, as a remedy for neuralgia. It is not unlikely that Ross' observation will be confirmed if the dyes are known to be a cause of neuritis.

[1] Die Schwefelkohlenstoff-vergiftungen der Gummi arbeiter. Leipzig, 1899; also E. Koster, Arch. für Psych., xxxiii, 3.
[2] American Jour. of the Med. Sci., April, 1901.

I fear that I have taken too much time in the consideration of these toxic cases of neuritis. But it has seemed to me necessary, for I wish to emphasize our duty as physicians to protect the workmen who are ignorant of these dangers attendant upon their employment. In many industries it has been found needful to insure healthful surroundings by legal enactment. The restrictions have resulted in the banishment of many forms of chronic poisoning. If it is necessary to call attention to further danger to the working class it is surely our duty to realize these dangers. Hence, as new perils are discovered, we should investigate their effects and if needed devise appropriate remedies.

II. We turn now to the second class of cases of multiple neuritis, viz., toxemia from infection. In this class are included all cases due to the development and action in the organism of some bacterial poison either of external or of internal origin. Multiple neuritis is known to occur as an accompaniment of, or as a sequel to, diphtheria, severe pharyngitis, the grippe, typhoid, typhus, malarial and scarlet fevers, measles, mumps, whooping-cough and smallpox, pneumonia, erysipelas, gonorrhea, puerperal fever, septicemia of any origin. We may include in this class the epidemic form known as beri-beri and also leprous neuritis. The literature upon the subject of these various cases of multiple neuritis has increased enormously within the past ten years. In the volume of Nothnagel's Specielle Pathologie und Therapie, prepared by Remak on neuritis, several hundred articles are cited. There can be no doubt whatever that the majority of cases of paralysis, of severe painful affections, and of vasomotor disturbances which have been recognized as complications of these infectious diseases are due to multiple neuritis. They have all the characteristics of that affection and like it they usually terminate in recovery in the course of time. Many cases are limited in extent to one or two nerves. Others are widespread, involving many nerves, but all can be traced to some toxic agent of infectious origin. In some cases the neuritis occurs during the course of the infectious disease. In the majority of cases it develops later as a sequel, due in all probability either to a toxin left in the blood, or to the fact that the nerves resist for a long time the action of a toxin which finally overcomes them.

I cannot do more than enumerate these causes, but in passing I wish to remark that since the use of antitoxin in diphtheria the number of cases of diphtheritic paralysis is decidedly less. I wish to emphasize the frequency of neuritis following grippe. I have observed all the various types, the paralytic, the painful neuralgic, the pseudo-ataxic and the vasomotor type, and I find recovery in these cases to be very slow. I have thought that many cases following typhoid might be explained as alcoholic in origin, since stimulants are used very freely and have been particularly needed in many cases which subsequently showed neuritis. The ordinary forms of malaria as seen here rarely

are followed by multiple neuritis, but the severer types seen in the tropics, dengue fever especially, are liable to cause neuritis. I have already seen two bad cases sent home from the Philippine Islands. Foreign observers have seen cases following the children's fevers named, but they are certainly rare in this country. Sufficient attention has not, however, been paid to the cases traceable to septic conditions and to gonorrhœ A long-continued suppuration in a tooth, in the ear, in the nasal cavity, or any collection of pus, or gonorrhea, and the condition of the blood which leads to a series of boils or carbuncles are certainly competent causes of multiple neuritis. It is not well to assign the case to the category of unknown causes until these factors are wholly excluded.

It has seemed very probable to several authors that some of the cases of neuritis hitherto classed among cases of unknown origin are really due to an infectious agent. These cases show many characteristics of an acute infectious disease. They begin with chill and fever, a temperature of 103° F. having been often recorded, and with all the accompanying symptoms of an acute febrile movement, viz., malaise, gastro-intestinal irritation, headache, profuse sweating, rapid pulse, catarrhal states of the pharynx, larynx and bronchi, dark heavy urine, and a swelling of the spleen. The latter symptom has been considered by Strumpell, Caspari and J. J. Putnam as proof positive of an infectious origin of the disease. It should be looked for in any case. The pain in the joints which attends these cases has led to their being considered rheumatic, but this I think is erroneous.

Beri-beri or kakke is a form of neuritis of which we are likely to see many cases, especially on our Western coast, since our acquisition of the Philippine Islands, in which it is always endemic and often epidemic. No positive proof has yet been offered of its origin from a micro-organism, though several investigators claim to have discovered a characteristic bacillus. Many believe it to be due to a diet in which rice predominates, and it is a fact that the Japanese Navy has been quite free from the disease since its diet-sheet has been extended and made to include meat, green vegetables, and fruit. But this diet theory is discarded by Scheube,[1] who adheres to the infectious theory of the disease.

III. The third class of causes of multiple neuritis is allied to the second class, for while not truly toxemic or infectious it is a class which Remak terms dyscrasic. There are certain discases the presence of which in the system predisposes it to nervous affections and among these affections it is now necessary to include multiple neuritis. Some of these diseases are in themselves of bacterial origin. Thus, tuberculosis is surely and rheumatism possibly so. Others are due to disordered states of the blood consequent upon some inactivity in other organs. Thus, diabetes, gout, and rheumatism are conditions which notably predispose to neuritis. Carcinoma, arteriosclerosis, and the senile condition are also known to incline to the development of neuritis. Hence, we can form a class of cases of neuritis which is to be traced to some other disease present in the body. In tuberculous patients the multiple neuritis is not due to the invasion of the nerves by the bacillus, for most careful postmortem investigation has never revealed its presence in the nerve-sheaths; but the lowered vitality of the patient seems to impair the nutrition of the neurons, which suffer first in their extreme peripheral parts so far removed from the nutrient center in the cell-body.

In rheumatic patients a coincidence of acute articular rheumatism and acute multiple neuritis is too common to be an accident and in either condition the other is extremely liable to occur. Hence, we have to admit a rheumatic variety. The Germans speak of the form of neuritis due to exposure to cold as "rheumatic." That such exposure is a sufficient cause is admitted. One of the worst cases I have seen developed in a man who, while asleep under a tree, was suddenly drenched by a shower and severely chilled. The next day he was paralyzed and had all the symptoms of multiple neuritis for several months. The condition produced by a draft of cold air or by exposure to cold is one which causes either immediate changes in the blood or peculiar susceptibility in the body-cells to the action of otherwise innocuous agents in the blood or to extraneous poisons of bacterial or of some other origin, and this must be admitted as a cause not only of neuralgia, of local neuritis like facial palsy, but also of multiple neuritis.

In diabetic patients localized mononeuritis is a very common occurrence. All authorities have emphasized this fact. But, while neuralgia, ulnar neuritis, crural and sciatic neuritis, etc., are frequently observed, general multiple neuritis is seldom seen. Leyden, Raymond, Buzzard and Charcot have described the only cases not open to criticism. I have never seen such a case.

In gouty patients also mononeuritis is far more common than multiple neuritis; in fact, but a few cases of the latter have been recorded. I have seen one case which deserves to be cited because of its unusual features.

The disease began with a severe itching and burning sensation about the toenails and upon the dorsum of the right foot, which soon developed in the left foot also. This itching and burning sensation soon extended up both legs to the knee, but was not at first attended by any change in the appearance of the skin or by actual anesthesia. After several remissions the symptoms became more intense and the burning and itching were accompanied by the appearance of a crop of minute vesicles. The feet then became swollen, the skin became glossy, red and extremely tender to the slightest touch and the sensation was one of great pain throughout both lower ex-

[1] Scheube. Beri-beri, Jena, 1894; and Die Krankheiten der Warmen Lander. 1899.

tremities. Any moist dressing upon the surface intensified the pain, but dry dressings or oily applications seemed to give relief. Large serous blebs formed upon the soles of the feet and about the toes, and there were considerable eczematous exudation and a scaly appearance of the skin of the entire legs. After this condition had lasted for three months similar itching and burning began in the hands about the fingers with very marked deep-seated paresthesia. Fine vesicular pin-point elevations in the skin of the hands also appeared, but these did not go on to the formation of blebs as in the feet. After two months the skin of the legs had become thickened, cracked, and shiny with crusts all over the surface, and when these had peeled off the surface was red and very sensitive to light pressure. The nails of the toes were thickened, rough, striated and black. It was said that they had not grown at all during six months. Tactile sensibility was diminished over both feet and both legs, but any touch was attended by great pain. The muscles of the feet and legs became extremely atrophied and were almost entirely paralyzed; no electrical examination could be made on account of the extreme sensitiveness. At this time sciatica as high as the buttocks was complained of. The knee-jerks, at first exaggerated, were subsequently lost.

When I saw the patient, a woman of about fifty years of age, with Dr. W. H. Draper, seven months after the onset, she was unable to stand or to bear her feet upon the floor, but the paralysis had subsided and she could move her ankles, but could not move her toes. There was very marked tenderness to touch over both legs and upon both feet, and the tenderness upon the nerves on the soles of the feet was extreme. The skin of the feet was dry, scaly and cracked. The nails were badly discolored, ridged and dark and rough, excepting near the matrix, where a new growth of normal nail, about one-half inch in depth, had begun. Any covering applied to the feet caused intense burning and itching, so that she kept the feet entirely uncovered both day and night. There was nothing in the way of local treatment that relieved this itching and burning, though every form of local application had been tried. The ball of the foot was red, the rest of the foot white, but during an attack of pain the feet became scarlet, or sometimes became very much more pallid than usual. It was evident that the condition in the feet was that of erythromelalgia.

A similar burning sensation and itching were felt in the hands from time to time, but there was no apparent malnutrition of the skin.

The patient came of a very gouty family and had many indications of the presence of gout, and all these symptoms gradually subsided in the course of a year, under treatment directed exclusively to the gouty state, namely, dietetic treatment and alkalies given freely. The coal-tar products appeared to give some little relief to the local symptoms. I have seen the patient several times in the past five years and there has been no return of the affection.

I have seen several other cases that are quite similar to this in their symptoms and course and have no doubt that they can be classed together as gouty neuritis.

In carcinomatous patients, as in the tuberculous, any form of neuritis is to be traced to the general malnutrition. In old people, especially in those who are the subjects of arterial atheroma and sclerosis, general neuritis is responsible for many symptoms of feebleness and paralysis. Some of the cases described as senile paraplegia are undoubtedly cases of multiple neuritis. And the mere establishment of the cause should not in these cases lead to too serious a prognosis. I have watched a case this summer in the practice of Dr. R. B. Kimball, in which a gradual recovery from a state of total paralysis of both arms and both legs has ensued, although the patient was seventy-six years old, was the victim of a chronic arthritis deformans, and had extensive gangrene of one leg as a complication. It was interesting to observe that the rigid deformities due to the arthritis were relaxed during the course of the paralysis, but returned as that disease passed off. Oppenheim and Schlesinger have also seen gangrene as a complication of senile neuritis and regard it as very serious in old persons. In this case skin-grafting proved successful in spite of a very deep slough as large as one's hand.

The question of the existence of a syphilitic multiple neuritis has been raised and was recently discussed before the New York Neurological Society. The members agreed that they had never seen such a case and it is probable that syphilis does not enter as a causative factor in general multiple neuritis, though it may be the cause of local gummy swellings in the nerve-trunks. Cestan[1] has recently reported two cases and has found five others in the literature.

IV. Lastly we have to admit in many cases of multiple neuritis that no cause can be discovered. These are still termed "idiopathic" cases, but as the knowledge of the causes of the disease increases this class diminishes. I have already suggested that some cases formerly considered as belonging to this class are really infectious in nature. I would suggest that some still so considered are really due to auto-intoxication from the products of gastro-intestinal fermentation. Such a toxemia is now admitted as a cause of many serious nervous symptoms, of chronic recurrent headaches, of many neuralgias, of convulsions. May it be a cause of neuritis? There are cases of an acute general paralysis sudden in onset, transient in character, rapid in recovery, presenting the peripheral character of neuritis lacking evidence of central lesion. Such cases observed by Westphal, by Holt, by Mitchell, are too well authenticated to be disregarded. They point to a sudden suspension of function of the peripheral nerves under the form of intoxication.

[1] Nouv. Icon. photo. de la Salpêtrière, xiii, p. 153.

They do not always go on to neuritis, but they may so terminate. Possibly these cases, like cases of migraine, may be due to some poison in the blood produced within the body. If so, these cases must be transferred to the toxemic class. I do not think we can pay too great attention to searching for the cause in these cases. Yet that some baffle an inquiry is illustrated by the following case:

A. A. B., born in 1877, a young man of healthy parentage and of fine general physique; without any history of specific disease or of any bad habits, was sent into the Presbyterian Hospital on October 7, 1897, being then in a state of general motor and sensory paralysis involving all the limbs.

His first illness of any severity was a similar attack of general paralysis which occurred in 1892. In the summer of that year, while living a healthy out-of-door life, not drinking at all, and taking no drugs, he noticed a clumsiness of his hands, a tendency to drop things, and a feeling of unusual fatigue in his legs, which was soon followed by inability to stand on his toes. These symptoms were not attended by pain nor by any general constitutional disturbance. They increased, however, very rapidly to the point of absolute paralysis, and in three weeks after they were first noticed he was unable to use his hands to feed himself, or to walk or to stand alone. His control of his bladder and rectum remained normal, and except for his muscular weakness and a sensation of numbness in his limbs he felt well. He was sent for treatment to a sanitarium, where he remained for three months, but as he did not improve he was then, in October, 1892, taken to St. Luke's Hospital, where he was examined by the late Dr. Walter Vought and by me. At that time he was found to have a total paralysis of all the muscles below the knees and elbows, with considerable atrophy in these muscles, and a loss of faradic excitability. The reflexes were absent in the paralyzed muscles. The muscles of the upper part of the limbs were also weak, but voluntary motion was not suspended. Such motion, however, as was possible was ataxic and uncertain. The trunk muscles had not escaped, and he was unable to turn in bed or to sit up. There were partial wrist-drop, complete foot-drop, some tenderness along the muscles of the calves and of the forearms, but no sensory disturbance of any kind.

Under general tonic treatment with massage and electricity to the paralyzed muscles, he soon began to improve, and, after a month, was able to go home, though he still could not stand alone or feed himself. His recovery was, however, continuous and rapid, and in June, 1893, he reported that he had regained complete power in all his muscles, and was quite well except for some shaking of his hands (ataxia?) at times.

In August, 1894, he was readmitted to St. Luke's Hospital in about the same condition in which he had been on his first admission. The second attack had begun in July, and had gone on rapidly to almost total paralysis, again without pain or sensory disturbance save some numbness, and without any affection of the bladder or rectum. He was seen by Dr. Peterson in August, 1894, and by me in September, and we agreed upon the diagnosis of a multiple neuritis, but were unable to ascertain any cause. His progress to recovery was slow but continuous. In November he was able to leave the hospital, and in April, 1895, he reported himself as having regained complete power in all his muscles, though he complained of some formication and tremor in the right arm and hand. This gradually passed off.

On September 20, 1897, he presented himself at my office and complained of some numbness of his fingers and toes, of an awkwardness in fine motions, and a feeling of weakness in the hands and fatigue on walking far. I found a slight anesthesia to touch, cold and heat and pain in the fingers, a decided weakness of the interossei of the hands, but no other symptoms of disease, careful examination of every organ being negative, and his appearance being that of a young athlete well developed in every respect. We were both, however, alarmed at the prospect of a return of his paralysis, and he consented to a life of quiet and of care in diet, with the use of strong nerve tonics and of cod-liver oil. But these precautions were of no avail, and in the course of a month he had developed an absolutely total paralysis of all the muscles of the extremities with rapid atrophy and loss of faradic reaction. The trunk muscles and muscles of the head and neck were also invaded. He could not sit up or turn in bed. His external ocular muscles were weak, so that he had a slight internal strabismus, and saw double. His speech was noticeably thick and pronunciation was imperfect, and soon after his admission to the hospital deglutition became affected, so that he could swallow only with great difficulty. Then his respiration became suddenly unnatural, and it was found that there was no spontaneous action of the diaphragm. For two weeks his respiratory movements were wholly of the type seen in volitional labored breathing, and during this time he slept little, as respiration became uncertain and irregular when the conscious effort ceased. His pulse at this time was extremely rapid, but never intermittent or irregular. His bladder and rectum were always under perfect control. His mind was always clear and his courage good. Preparation was made to maintain artificial respiration, if needed, but this was never necessary. After two weeks the respiratory motions seemed gradually to become more natural, the diaphragm began to work again at night during sleep, and after a month its action at all times was natural. During the following month, after the improvement set in, it advanced rapidly in all the muscles, the muscles of the trunk and near the trunk regaining their power sooner than those of the distal parts of the extremities. It seemed safe to allow him to go

home November 25th, and he reported a steady improvement. At the height of his paralysis there was an anesthesia to touch, temperature and pain as high as his elbows and knees, but not in his face or on his trunk. The special senses were normal. He has had no recurence during the past four years, and is at present in perfect health.

I have not found recorded many cases of recurrent attacks of neuritis. Leran, however, has published the history of one patient who had suffered from nine attacks in successive years, no cause being found.

This finishes the list of causes thus far determined. It must, however, be added that in some cases of neuritis a double causation may be ascertained. Thus, it is well known that alcoholic subjects are more liable to arsenic- and lead-poisoning than non-alcoholics. It has been observed that alcoholic neuritis often develops in an individual subsequently to an attack of the grippe, typhoid or other infectious diseases, though the amount of alcohol taken is not increased. Hence, it is not wholly sufficient to ascertain one cause in a patient, and we should not be satisfied that we have determined the exact etiology of the affection in any patient until we have elicited every possible factor in the case.

CRIMINAL ABORTION.

BY E. STUVER, M.SC., M.D., PH.D.,
OF FORT COLLINS, COLO.:
MEMBER INTERNATIONAL MEDICAL CONGRESS (BERLIN); FELLOW AMERICAN ACADEMY OF MEDICINE.

I believe that the distinction between the terms abortion and miscarriage should be made on moral and ethical grounds rather than be determined by the length of time pregnancy has continued, as has been heretofore done. I would, therefore, define abortion as the deliberate and intentional interruption of pregnancy before viability of the fœtus has been attained.

Every physician in active general practice will, I believe, bear me out in the statement that this dread crime is widespread among all nations and people; that it has invaded all ranks and classes of society from the highest to the lowest; that it is not confined to the criminal classes alone, but has penetrated the most exclusive abodes of luxury, splendor and fashion, and has even been admitted to the homes of those active in church and religious work, and supposedly surrounded by a halo of sanctity. My remarks shall have no reference whatever to those rare cases in which, in order to save the life of the mother, it is necessary to sacrifice the child, but I do desire most emphatically to insist that in all cases in which such a condition exists the attending physician call to his aid and assistance one or more competent physicians in good standing, not only for his own protection, but in order to impress upon the family and the community the seriousness and gravity of such an undertaking.

In order to appreciate the far-reaching consequences of this widespread crime, let us consider some of its physical, mental and moral effects on the individual and upon the race.

When one considers the lives destroyed by the abortionist the life losses of the Spanish-American and Boer wars pale into insignificance; but such evils are of comparatively slight importance beside the obtunding of the moral nature, the turpitude and race degeneracy consequent on this most insidious and degrading of all crimes. These truths have long been appreciated by the conscientious and thinking members of our profession. The late lamented and brilliant Dr. J. T. Whittaker, in an address (*Journal of the American Medical Association*, April 11, 1896, p. 700), spoke as follows: "Physical corruption is never so bad as is moral corruption. All history shows that though a plague may devastate, it is immorality alone that can destroy a nation. . . . Rome fell not because of the plagues, not because of the Goths and Vandals, but because of the failure in the crop of Roman children."

If failure in the crop of children is a sign of national decay and degradation, then surely the so-called progressive civilized nations are on the down grade. According to the latest census reports, there has been a decided falling off in the birth-rate of the principal European countries, not only in France, of which decrease we have heard so much, but also in England, Germany, and among other leading nations. The same thing is true to an alarming extent of our own country, especially in the American element or the old native stock: and, were it not for the fact that there is a constant influx of foreigners and a high birth-rate among these people, our rapid increase of population would suddenly cease.

As to how great an influence abortion has exerted in lowering the birth-rate in our own and in other countries, none can speak definitely, but when we consider the number of young lives sacrificed every year and the immense amount of disease and sterility following this infamous practice, I believe I am justified in claiming that abortion is a prominent factor in the retardation of national growth and an insidious cause sapping our physical, mental and moral strength as a nation. War, by destroying the young, strong, vigorous and robust, and by allowing the old, weak and diseased to propagate their kind, lowers the strength and vitality of a nation. This truth is vividly shown by the loss in stature and in the physical degeneracy of the French people since the Napoleonic wars, and to a less marked extent in our own country since the late Civil War. Abortion, by killing, crippling and sterilizing many of the strong and vigorous young women, has an effect analogous to that of war, and necessarily produces more or less national and race degeneracy.

The truth of Pope's forceful lines,

> "Vice is a monster of so frightful mien
> As to be hated needs but to be seen,
> But seen too oft, familiar with her face,
> We first endure, then pity, then embrace"—

could nowhere find a stronger confirmation than in connection with the degrading effects of criminal abortion on the moral nature. Many women, who in other respects are esteemed for their beautiful traits of character, their graces both of mind and of body, who are the bulwarks of church and society, who are actively engaged in philanthropical, educational and other good works, when brought face to face with this condition will resort to all kinds of sophistry, subterfuge, to any means whatsoever to induce the physician to murder their unborn offspring. While heretofore there has been a widespread indifference on the part of the public, and even of our courts, as to the importance of this matter, I am glad to note recently a more thorough appreciation of the gravity of the offense by some of our highest State courts. The Supreme Court of the State of Idaho, in the case of the State *vs.* Alcorn says: "An unnatural abortion, brought about by means of drugs or instruments, violates the Divine law, the law of Nature, decency, the best interests of society, the criminal statutes of the State, and not only is destructive of a life unborn, but places in jeopardy the life of a human being, the pregnant woman." This court also holds that "where an unnatural abortion is sought to be caused by the use of instruments or drugs and death results, an abortion not being necessary to save the life of the woman, such acts under the statutes constitute the crime of murder in the second degree." (*Journal American Medical Association,* July 6, 1901, p. 61.)

The question naturally arises, What can be done to prevent the perpetration of this crime, and to obviate its physical and moral evil consequences? Before we can correct an evil, we should have a clear conception of the causes which produce it. As I have indicated in a previous article, entitled "How Can We Prevent the Slaughter of the Innocents?" printed in the *Charlotte Medical Journal,* February, 1898, I believe the principal causes are as follows: (1) Hereditary vestiges of pre-existing savage or barbarous instincts and practices. (2) Ignorance of the biological fact that from the moment of conception the developing embryo contains all the potential powers of the fully-developed individual. (3) Apathy, or a spirit of *laissez faire,* on the part of the great majority of the people. (4) Incompetence on the part of legislators to comprehend the true significance of the subject, and the consequent futility of the laws enacted by them to prevent the crime of abortion by adequate punishment thereof. (5) The inability, or disinclination, of judges to appreciate the rights of the embryo as an individual entity during the early stages of its development. (6) The ignorance, or disregard, of the subject on the part of teachers, ministers, druggists, and physicians, and the frequent complicity of the two latter classes in the perpetration of the crime. (7) Ignorance of the physical dangers and the moral degradation inevitably attendant on this offense.

Prevention.—The question naturally arises, How can this evil be prevented, or at least mitigated? In the first place, every true physician should be aroused to a keen appreciation of the moral and professional importance of this subject, and he, in turn, should strongly impress upon every one who applies to him for such service that, from a biological standpoint, the operation, unless absolutely necessary to save the mother's life, is plain, simple murder and cannot be extenuated in any manner whatsoever. At the same time, the terrible physical evils which may and do frequently follow should be strongly impressed upon the mind of the applicant and the moral infamy of the offense seared into her very soul, if such a thing be possible. Then, too, every medical society in the land should set the seal of its emphatic condemnation on this offense, and should ignominiously expel any physician guilty either of its perpetration or of connivance thereto. Every physician should be given to understand that he dare not produce abortions upon prostitutes, or upon those who, for convenience or social indulgences, would violate Nature's laws, and at the same time retain his position as an honorable professional man or woman.

Nor is it sufficient that the physician merely occupy the negative position of refusing to perform such operation. He should embrace every fitting opportunity to impress its importance upon others. Legislators and judges should be taught the biological facts on which life rests, so that laws may be framed and decisions rendered in accordance with the necessities of the case. Ministers should, likewise, be instructed and aroused to an appreciation of the enormity of the crime and its devastating consequences. Their calling affords them many opportunities to point out vividly the physical dangers and moral turpitude of the offense. They are in a position to do much good, and their sympathy and co-operation should be secured in overcoming the evil. Teachers in our higher institutions of learning can, by instilling correct moral principles into the minds of students, do much toward preventing this baleful practice.

Finally, laws, with severe penalties for their contravention, should be enacted prohibiting newspapers from advertising and druggists from selling abortifacient remedies, except on prescription of properly-licensed physicians. Such laws, if properly enacted and rigidly enforced, would, I believe, prevent a great many of these crimes, and have a very salutary effect in awakening the people to the enormity of this offense.

Unique Case in Bankruptcy.—A petition in involuntary bankruptcy has been filed against Samuel Jacobi of 1595 Broadway by the following creditors: James E. Kelly, $500; Alexander Strong, $200, and William H. Bates, $125. The creditors are physicians and their claims are for medical attendance and expert testimony. This is said to be the first instance of the kind in which three physicians have appeared as creditors.

ON THE USE OF THE OPIATES, ESPECIALLY MORPHINE.[1]

BY OSCAR C. YOUNG, M.D.,
OF CHARLESTOWN, N.H.

I AM induced to write a short paper on the rational uses of the opiates, partly because I have been a patient and have suffered as intense pain as it is possible for any patient that any of you will ever be called upon to relieve from the tortures of physical agony, even if only temporarily, has ever suffered, and partly because there is a growing tendency to the extreme of treating human ailments by any and all other methods except by the administration of the common and well-tried remedies.

I will illustrate the latter statement by calling your attention to the abolition of the former practice of blood-letting for plethora and anemia, alike for protracted fevers and for pneumonia, without discrimination, and now when we should bleed for acute congestive conditions, or apoplexy, we do nothing of the sort. It is true that the practise of some, by the administration of aconite, belladonna or veratrum viride, of "bleeding them into their own veins," is a substitute for literal blood-letting, but as there has been such a great reaction to the opposite extreme, the former one in this practise, so is there a growing tendency to the abolition of the use of drugs. And if this is true of any drug—and I think none will deny that it is so—it is certainly true of the most potent pain-extinguishers, the opiates.

I am well aware that I differ in opinion from many and very able men in respect to the uses to which the opiates may be put; and if an expression of this opinion from any who may read this paper will lead to a fuller appreciation of their value, my object in writing this paper will have been accomplished.

Just a word to any who may have become extremists by abolishing drugs from their therapeutic armamentarium. Our remedies to-day are better understood and our knowledge of their rational uses is better appreciated than ever before, and the practitioner of medicine who fails to get results from the use of drugs in his cases, considered as a whole, has failed to appreciate the connection between the proper drug and the condition he is seeking to relieve. The chief cause for the reaction against morphine and opium is because a few decades ago it was given so indiscriminately by the general practitioner that many, very many, became addicted to its use; the habit was formed, and the person's life thus ruined; for of all narcotic habits, the alcohol habit included, I believe this habit is the very worst. Thus, the present generation has been so thoroughly warned, both by teaching at college and by observation, that now they are in many instances so very afraid to give it, even for the worst pain, that the patient suffers agonies worse than any hell for want of one-eighth of a grain of morphine. And, on the other hand, it is sometimes used so indiscriminately that a dose is thrown into the patient for a common pain or ache which could be endured until a milder remedy would relieve the suffering; the latter, however, is not a common occurrence.

I believe it wiser to take a few minutes more in looking over our patients—and it won't take many more—and ascertain the cause of their suffering sufficiently to enable us to judge intelligently as to whether they need morphine hypodermically or whether a small dose by mouth will not be best, or if a dose of bromide or sulphonal for sleep will not suffice, or if an acetanilid compound tablet or one of the milder analgesics will not answer quite as well to relieve pain, if pain there be.

The present danger of the practitioner's inducing the habit in a patient is, I believe, overdrawn. It is true that it is one indulged in by a great many, but it is also true that the physician is not at fault nearly as often as formerly, for now we *will not* give it after we recognize that an analgesic or hypnotic is required for a much longer time than two or three weeks, and as a rule we do not tell what we are giving the patient.

Not long since I was called to an adjoining town to see a patient suffering intense pain. I inquired if he had ever taken morphine. The reply was, "Oh yes, Dr. T. gave it to me once. Dr. T. was a great fellow to give that, you know." But let me say right here that since the above Dr. T. left this town I have been there a good deal and have never found a morphine habitué. Why? Because he gave them something which stopped their aches and pains and then stopped.

Untoward Effects.—When opium is given to some persons it produces for some hours marked wakefulness followed by sleep, and in many patients it produces, after its primary effect has worn off, great nausea, followed in some instances by vomiting. The mental effect in some instances may be simply overwhelming. By far the best method of preventing these undesirable effects of opium or its derivatives is to administer $^1/_{200}$ gr. of nitroglycerin at the same time that we give the opiate.

One of the chief causes of the nausea is the change in the body of morphine into oxy-dimorphine, which is eliminated into the stomach and there reabsorbed and then induces the secondary effects. It is also a fact that these symptoms can be largely done away with by giving at the same time 20 grains of bromide of potassium, and by using the preparations that are largely devoid of narcotine, such as the deodorized tincture or the deodorized opium itself.

The action of opium upon man and the lower animals varies with the degree of intelligence or cerebral development. It quiets the brain and excites the spinal cord. The dominant action is to produce nervous sedation in small doses and to induce sleep in larger amounts. Sometimes, however, in persons accustomed to its use it pro-

[1] Read before New Hampshire State Medical Society, 1901.

duces a state of restless insomnia or quiet, wakeful apathy. Small therapeutic doses have no effect on the circulation, but larger ones slow the pulse, increase its force, and slightly raise arterial tension—and here it is fitting to say that some object to giving one-eighth of a grain of morphine in severe cases of pleuropneumonia, with the most intense suffering at every breath, because of an imaginary depressing effect upon the heart.

I have in mind a case that ultimately terminated fatally, in which the physician asked the patient to bear the pain if possible without the morhpine; she did, until death released her. Think you that one or two hypodermics of one-eighth of a grain of morphine and $^1/_{200}$ of a grain of atropine in twenty-four hours would have hastened death? Not so, but it would have given such relief and perhaps aided in supporting the patient past the crisis by giving some rest.

In very minute doses opium is a feeble stimulant to the respiration, or at least not a depressant. In large doses or overdoses it is one of the most potent depressants and paralyzants of the respiratory center, causing death by this action. The bodily temperature is raised slightly by full doses and lowered by poisonous amounts of opium. It diminishes tissue waste. It is eliminated by way of the intestines and kidneys, but experiments have proven that most of it is destroyed by oxidation in the liver and tissues.

Morphine is chiefly eliminated by the stomach, and if in cases of poisoning by this drug the stomach is frequently washed out recovery is much aided by thus preventing reabsorption.

In ordinary amounts it diminishes peristalsis of the stomach and intestines by stimulating the splanchnic inhibitory fibers of these organs. In large doses it paralyzes and increases peristalsis —the latter producing diarrhea, the former constipation. Opium checks the secretion of every organ except that of the skin.

Opium is used for the relief of five conditions, (1) pain, (2) insomnia, (3) irritation and inflammation, (4) oversecretion, and (5) systemic strain.

Opiates are the best agents that we possess for the relief of all forms of pain, except possibly some forms of neuralgia which are relieved very readily by antipyrin or its fellow compounds, which excell the opiates because they have no bad after-effects; and still we always have in mind that its depressing tendency may be an objection to any coal-tar product. Still it is to be remembered that there is no agent so potent for the intense neuralgias as a hypodermic of morphine. There is one form of pain in which opium must not be used—cerebral congestion and cerebritis, for it will aggravate the trouble. In acute traumatic meningitis, however, it does good, either alone or combined with mercury in sthenic cases.

In the various colics, renal, hepatic, etc., nothing acts so well as morphine. In dysmenorrhea, morphine associated with belladonna relieves the spasm of pain, and yet they so counteract each other that there are no after-effects sufficient to contra-indicate their use.

For the relief of all forms of intense pain in any disease under ordinary conditions, there need be no hesitancy in administering hypodermically a moderate dose of morphine. If the patient has a dread of the needle, or if for any reason it is thought best not to give it so, then give in hot water by mouth, with or without the addition of whisky or brandy. Or we may give deodorized tincture of opium—an excellent agent—in the same manner as the morphine, by mounth. If neither of these is desired, give the fluid extract or tincture of opium in starch-water by enema. If the pain is in the pelvis this last is the best method of administration. In violent sciatica, inject the morphine over the affected area.

In other cases of superficial inflammation, treat by applying locally lead-water and laudanum. But remember to be on guard about forming the habit in patients prone to repeated attacks of pain.

Upon inflammation opium seems to exert some influence not very easy of explanation; both large and small doses are of value upon inflamed serous membranes, as in meningitis and pericarditis. It allays the nervous cough following hemoptysis and quiets the excitement, and thus has the double effect of relieving the patient's fears and diminishing the danger of aggravating and causing another attack of bleeding. Whenever a cough is in excess, *i. e.*, greater than is necessary to free the lungs from mucus, morphine may well be given in small doses, but if the number of râles increases by its use it must be stopped, as an increase of the number of râles indicates an increase in the accumulation of mucus.

In muscular rheumatism and immediately after a so-called ordinary cold, nothing is better than hot internal and external applications, and four or five hourly-doses of two grains of Dover's powder.

In serous diarrhea, diabetes insipidus and diabetes mellitus, and in the treatment of oversecretion of any secreting surface except the skin, opiates may well be used.

The employment of opium, morphine or codeine is a very valuable form of treatment for diabetes mellitus. Increase the dose very rapidly, as its effect is produced only by rapidly ascending amounts. Diabetic patients seem singularly immune to the nervous influence of this drug or its alkaloids. Crude opium is more effective in diabetes than either morphine or codeine. None of them probably cures the disease, but so modifies it as to make life bearable and happy, for the sugar is decreased in many cases and the sense of excessive hunger, thirst and nervous idditability is put aside. Itching of the skin in this class of patients is relieved by this treatment.

Opiates may be used to check mucous diarrhea after the intestinal canal has first been swept clean of mucus by a purge. Minute doses of $^1/_{80}$

to $^1/_{50}$ grain of morphine hypodermically will often cure an attack of serous diarrhea in children. The camphorated tincture is especially valuable in diarrheas, because it contains camphor and a volatile oil, both of which act as antiseptics.

In prolonged strain upon the system, as in great physical or nervous effort, or more frequently in old age to smooth out the cares of the remaining years of life and decrease worry, opium is useful, but not to be much used in young persons for fear of causing the habit.

In advanced phthisis it is of especial value to give just enough to relieve from pain and excessive cough, but care should be taken not to give enough to choke the patient and thus hasten death.

In heart disease, especially of the mitral valves, the patient often breathes very well when awake, but as soon as he falls asleep he starts up gasping for breath, and while it is especially true that morphine greatly relieves this very distressing symptom in mitral disease, it is of value in difficult breathing in all forms of heart disease, and should be always tried with discretion. It is contra-indicated in fatty degeneration of the heart.

Give it hypodermically in moderate doses if possible.

The use of opiates for sleeplessness I regard as one of the most important subjects for the general practitioner to keep in mind. There are plenty of remedies containing not a particle, or very little, of the danger that opium does of causing a habit, if the inability to sleep is due to any or every cause but pain. And although we have all tried some form of this drug to produce sleep when our patient is not in pain, we soon prescribe sulphonal, trional, or the bromides, or some remedy having similar action if we find that a hypnotic is to be needed long; and patients will do better, if not in pain, to take something other than morphine.

But let us place ourselves in the position of the patient and let us have many wakeful nights, due to a neuralgia or to some nerve injury, worn out with loss of sleep, too tired even to sleep if not in pain, and still suffering agonies from the pain, how long would one of us want to get along with a little dose of codeine, or bromide, or hyoscine? We wouldn't endure it at all; we would simply get the morphine or the deodorized tincture and give ourselves a good dose and quiet the distress, and get some sleep.

I said we would get it ourselves; so we would if we were able to do so; but supposing it is our patient and we do not like to give opiates very well, and we come in and see him and observe his pulse and temperature and find him doing well on the whole, and think his talk about intense pain is exaggeration, because he has had so much pain that he is getting hysterical, and we imagine that he is craving a hypodermic, and so give him something else that does not touch the pain at all, and then he has another night such as the old time clergy would depict as the lowest Hades, and he goes on night after night like this; but gradually the injured or diseased nerve gets better, pain subsides, sleep is restored, and lo, the patient is cured, and we say how much better than if we had given him morphine; he would have wanted it right along, and we would have had an awful row with him to break it off.

Or, perhaps he has been *very* ill; the loss of sleep goes on night after night; he gets more and more exhausted, and dies. Because he was so ill? Possibly, but I'll venture to say many who are now dead might have been sustained by giving them sleep, by relieving the pain, and made to live by the use of a few doses of morphine.

I have had a trying personal experience in this very way. I was struck by an iron lever, ¾ of an inch in diameter, of a locomotive engine going at the rate of eighteen miles an hour, just where the sciatic nerve makes its exit from the pelvis. The inflamed original injury extended to the whole nerve. This is the largest and longest nerve in our anatomy, and there is plenty of opportunity to build up an ache, and the pain for weeks was something dreadful. During the first forty-eight hours I received ⅞ of a grain of morphine in seven hypodermics, and one week later one more of ⅛ grain. That was all the morphine administered. How I used to plead, beg, scold, and even cry for just one dose to relieve the intensity of the pain. I was obliged to lie on my back all the time for one week. I could not lift my head from the pillow, and tried to persuade a member of my family to bring me just one grain of opium. No, I could not have it, as it was thought best not to give me opiates; milder remedies which required two or three hours partially to relieve the pain were thought best for me. Were I to go through the same experience again I would a hundred times rather die than endure such pain, even if sure of recovery in the end.

I beg your pardon for alluding to myself, but what I suffered has made such a profound impression upon my mind that if I were to live to the age of Methuselah I could not forget it, and I mention it because some of you will have surgical patients whose suffering will be just as intense as mine was, and I beg of you, in the name of humanity and for the credit to yourself, that you will occasionally give some opiate to stop the pain and give them sleep. When they beg for relief with tears in their eyes, do not treat them as if they were morphine habitués or lunatics, and wanted the drug for its intoxicating effect, but treat them as you would want to be treated under the same conditions.

Unless you find some ill-effects from the drug after the first or second administration, do not hesitate to give ⅛ to ¼ grain once a day for one or two weeks, or even twice a day if necessary. But very often one injection every second or third day will suffice to give several hours of refreshing sleep, and the sharpness of the pain will have been dulled, so that another will not be needed for two or three days.

I remember in my own case how, after three

days of especially intense pain and after at last making myself understood, I was given ⅛ grain of morphine and inside of ten minutes I began to go to a beautiful place and soon was fast asleep. I shall never forget the world of good that one-eighth of a grain did me. The pain never returned again with such force as before, while under milder agents it had been growing more severe every day. In fact, after this one-eighth of a grain on the eighth day, I was able with the milder agents to control myself and, I believe, did not again ask for morphine.

If we have a patient of average intelligence, let us treat him as we would wish to be treated were he the doctor and we the patient.

GONORRHEA IN WOMEN.

BY J. B. KILLEBREW, M.D.,
OF MOBILE, ALA.

Gonorrhea in women is of great interest both to the medical profession and to society. Next to infection following labor, miscarriage or abortion, it is the cause of more suffering among women than any other agent. Probably, nearly half the cases of pelvic inflammation are of gonorrheal origin. This is to be greatly deplored for many reasons. In the majority of cases a woman contracts this loathsome disease innocently; and in many cases in which the damage done is not sufficient to produce invalidism, the function of the generative organs is so impaired as to cause sterility, thereby depriving the victim of the privileges of motherhood, the highest and noblest she possesses.

The sole causative germ is the gonococcus, but the infection is usually a mixed one. The disease may be contracted in many ways, usually by sexual intercourse with a male suffering from a gonorrheal urethritis. Any part of the genito-urinary tract may be involved, but those parts covered by stratified squamous epithelium, being more resistent to the invasion of the gonococcus, are not as often the seat of infection as those covered by cylindrical epithelium. Hence, it is more usual to see a gonorrheal urethritis and endocervicitis than it is to see a vulvitis or vaginitis. The vulvovaginal glands and the glands of the vestibule are frequently the seat of primary infection. From some one or more of these foci of infection the disease is very likely to spread to the remainder of the genital tract, producing endometritis, salpingitis, ovaritis and peritonitis. Especially is this true in untreated cases. This extension of the disease is by continuity of tissue and not through the lymphatics.

The symptoms of gonorrhea in the female are not often severe and do not give rise to much suffering before the infection reaches the endometrium. It often happens that a woman who has married a man with gleet will notice, after five or six days, that there is a slight burning pain upon urinating; some redness, swelling and soreness about the vulva, with a profuse discharge of pus which compels her to bathe frequently. Being ignorant, she will attribute the trouble to excessive intercourse; and as the suffering is not great she will not, because of modesty, make mention of it, but bear the annoyance with good grace. The menstrual flow will appear before the signs of inflammation have disappeared. For three or four days it will be normal. Then follow sharp lancinating pains in the uterus with severe cramps. The flow will increase in amount and three or four days after the onset of the severe symptoms there will be a most profuse, irritating yellow discharge. The entire pelvis will become tender, frequently so much so that she cannot bear to be touched. The pus is probably mixed with blood. The temperature rises to 100°-103° F., and the pulse ranges from 90 to 110. Such is a typical picture of an acute attack of gonorrhea from the time of infection until it reaches the peri-uterine structures. Uterine infection may take place at any time, but usually occurs at the menstrual period when the endometrium is exfoliated. Fortunately, in many cases, even when no treatment has been applied, the gonococci do not advance beyond the internal os. In this event the symptoms gradually subside, and in many cases disappear entirely. Proyer has examined the scrapings from the cervix of 100 clinic patients who had absolutely no discharge of pus and found the gonococcus present in 22. This demonstrates the fact that a woman may show no evidence of gonorrhea and still be in a condition to infect others and to become actively inflamed herself, if the cervix be subjected to any traumatism. This also makes clear the necessity for sterilizing the cervical canal, superficially at least, before passing the sound, in order to prevent carrying the germs into the uterine cavity. I make it an invariable practice to apply tincture of iodine to the cervical canal before passing the sound.

That the onset of this disease in women is insidious and the symptoms mild is much to be regretted. Were they of sufficient severity to compel her to seek medical aid while the infection is confined to the urethra, vulva and vagina, in most cases she would be easily and thoroughly cured. The ease with which local treatment can be applied would render this result the rule, but, after the infection has reached the interior of the uterus, the condition is widely different, and in my opinion it is never cured except by surgical means, and then often only after the generative organs have suffered much damage.

The symptoms of gonorrheal infection of the genital tract are similar to those of infection by other pus-producing bacteria, and a positive diagnosis cannot be made except with the microscope. Even then it is not always positive, as one sometimes fails to find the gonococcus in the discharge from a gonorrheal infection. When the gonococcus is found, of course, the diagnosis is unmistakable. In gonorrheal infection the discharge is usually very profuse and irritating. The gonococcus has a predilection for certain

structures, especially for the urethra, and nearly every case of purulent urethritis is of gonorrheal origin. When facilities for the microscopical examination of the discharge are not obtainable, the history of the case is the best guide in making a diagnosis.

The prognosis in those cases in which the infection is limited to the urethra, vulva and vagina is good: in all others it is doubtful.

The treatment may be considered under two heads, *viz.*, preventive and curative. So long as the customs of society permit men to have promiscuous and illicit intercourse with women without putting the brand of disgrace upon them, it will be impossible to eradicate the disease from among us. Legislation can do no good, since laws governing this question, if made, cannot be enforced in the present state of society, and a law that cannot be enforced is worse than no law at all. It is not the prostitutes nor the women of loose character whom we wish to protect, but those young women who innocently contract the disease from husbands suffering from chronic gonorrhea. Few men would marry when in a condition to infect others if they realized their condition and the dangers to which they would subject the woman whom they wish to make their life companion. Men often regard gonorrhea in far too light a manner. It is not uncommon to hear a man say that he "does not mind gonorrhea," that he would as soon have it as a "bad cold." In some cases the disease in man is not productive of very distressing symptoms and subsides in a few days. No pus is seen coming from the urethra and he is apparently well, but in many of these cases there will remain a latent infection which will be aroused to activity when the proper stimulant is applied. Men should be taught the danger and insidiousness of this affection and the widespread evil resulting therefrom. The importance of subjecting themselves to treatment early in the disease and of continuing treatment until every sign of infection has disappeared cannot be too strongly insisted upon.

Many men have a stricture as a result of an attack of gonorrhea. This they look upon as a harmless condition when in reality it is a very serious matter. In many cases of stricture there is, just posterior to the narrowing, a small, inflamed or ulcerated spot in which the gonococci are present, but are quiescent and give rise to no acute symptoms. The ulcerated surface may be so small and the discharge from it so slight that the amount accumulated during the intervals between micturition is not great enough to cause pus to appear at the meatus. A man may be in this condition for years and never see a drop of discharge from the urethra, and still be capable of infecting others. I do not believe that any man with a stricture should marry before he has been thoroughly cured. Many others marry when suffering from a gleety discharge, thinking the discharge innocent because it produces no acute symptoms in them, but this discharge often contains gonococci. These germs, which are quiescent and cause no trouble in a urethra which has become more or less immune to their action, are, nevertheless, capable of producing the most violent inflammation when introduced into a new field. In many instances the gonococci do disappear from the discharge and in such event it is harmless; but, as there is no positive way of determining when the gonococci are present and when they are not, it is always best to be on the safe side. No man suffering from any of the sequelæ of gonorrheal urethritis should marry. Much more good can be accomplished by education than by legislation at the present time, and it is the duty of all physicians to educate the people in this matter.

As before stated, the curative treatment of gonorrhea in women is comparatively easy while the infection is confined to the urethra, vulva and vagina. Treatment consists of rest, thorough cleansing by douches containing some antiseptic solution, and local applications. If the vagina or vulva be affected it should be douched every three or four hours with 1:5,000 bichloride solution or ¼-per-cent. lysol solution. Local application of 1-per-cent. nitrate of silver or 2-per-cent. protargol should be made to the urethra once every twenty-four hours. The solutions applied to the vulva, vagina and cervix should be stronger. For this purpose I employ tincture of iodine, or 5-per-cent. nitrate of silver. These applications should be made once a day for three or four days and then every second day until all evidences of inflammation have disappeared. If the cervix is enlarged and congested it should be depleted by local blood-letting once a day for two or three days. Should an abscess form in the vulvo-vaginal glands it should be opened and treated in the usual way.

The only question in the treatment of acute gonorrheal endometritis that admits of discussion is the advisability of curetting. I believe these cases should be curetted as soon as possible. Some operators are opposed to this procedure, claiming that complications are apt to occur. Complications do not follow a well-performed curettage nearly as often as they do intra-uterine irrigations or any other method of non-operative treatment. Curettage is done for endometritis produced by any other pyogenic bacteria and I can see no reason for discriminating in favor of the gonococcus. It is always well to remember that complications do sometimes follow curettage and to tell the patient or her friends of this possibility, so that you will not be censured should such occur. If the patient will not consent to operation, intra-uterine irrigation is the best method of treatment. If this is begun before the gonococci have penetrated the endometrium a cure may result, but does not always follow. I usually irrigate first with a 1:10,000 bichloride solution, to be followed immediately by a saturated solution of boric acid. This treatment should be repeated every twenty-four hours. In some cases the cervical canal is so small that irrigations cannot be given. Vaginal douches of ¼-

per-cent. lysol solution at a temperature of 110° to 120° F. should be given for fifteen or twenty minutes every two hours.

In nearly all cases of chronic gonorrheal endometritis the infection has extended to the periuterine structures and any treatment applied to the endometrium alone will not effect a cure. In these cases treatment should also be applied directly to the appendages. A well-performed curettage will, by removing the focus of infection, give some temporary relief in most cases, but there is usually a relapse. The treatment applied to the appendages in all cases, not of long standing, should be at first conservative. It can be applied through an incision in Douglas' cul-de-sac and will in many instances bring about a cure. Radical work should be done in cases in which conservative treatment has failed, in which there is extensive suppuration, and in cases of genital sclerosis.

The conservative treatment to be employed will vary with the condition found to exist upon inspecting the appendages through the cul-de-sac opening. It consists essentially of breaking up all adhesions, opening the fimbriated end of the tubes, wiping them out with iodoform gauze and securing drainage. In those cases in which the fimbriated end of the tubes cannot be opened it is best to do a salpingostomy.

Not all cases treated in this way will be cured, but some will, and as a secondary radical operation can be done in those cases in which failure follows the conservative treatment, without any increase of danger, I believe it our duty to try the conservative treatment first and to make every effort to save for the woman her generative organs.

In cases of pyosalpinx, unilateral or bilateral, in cases of genital sclerosis, and in those cases in which conservative treatment has failed, a complete vaginal hysterectomy should be done, using forceps instead of ligatures to control hemorrhage.

A CASE OF SPONTANEOUS RUPTURE OF THE EYEBALL.[1]

BY W. WHITEHEAD GILFILLAN, M.D.,

OF NEW YORK;

FELLOW OF THE NEW YORK ACADEMY OF MEDICINE; VISITING OPHTHALMIC SURGEON TO THE CITY AND FRENCH HOSPITALS; OCULIST TO THE SAILORS' SNUG HARBOR AND HOUSE OF REFUGE; ASSISTANT SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, ETC.

M. F., female, French, aged eighty-seven years, entered the French Hospital April 3, 1900. The patient was treated for paralysis agitans. Her mental, as well as physical, condition was very poor. As the ophthalmologist to the Hospital I was called to see her in November, 1900, to treat her for a slight catarrhal conjunctivitis of both eyes. At that time I noticed senile cataract in each eye, as well as large opacities of the cornea, but there was no sign of staphyloma. The vision in each eye was very poor, being only $^{1}/_{200}$. In the course of three weeks she was cured of the trouble with the conjunctiva. On February 27, 1901, at three o'clock in the afternoon, she complained of a very sharp pain on the left side of the head. At this time the patient was in bed, although a short time before she had been to the closet with an attendant. By the time the assistant house surgeon, Dr. Thomassen, reached her, there had been a large hemorrhage from the globe of the left eye, much larger than one usually gets in an operation for enucleation. The crystalline lens was lying on her left cheek, much vitreous had escaped, and a portion of the iris was prolapsed.

The attending surgeon to the hospital, Dr. George G. Van Schaick, was making his daily visit to the institution. He was called and came with the house surgeon, Dr. A. W. Haskell. Dr. Van Schaick decided to cut off all the vitreous and iris that was presenting at the wound. This was done and a bandage applied.

As I was out of town at the time, I did not see the patient until the following day. On examination I found that the opening in the cornea was in the center and seemed only large enough to allow the lens to pass through. It was horizontal and the edges were rough. There was much blood in the anterior chamber. The size of the eye was not diminished. The wound closed slowly, it being six weeks before the cornea was completely healed.

On April 28, 1901, the patient was transferred to Bellevue Hospital. I was anxious to get the eye, if the patient died, and have a microscopic examination made. On July 1st I took up my service at the City Hospital, Blackwell's Island, and thought I might see the patient there, as most chronic cases are sent there from Bellevue. She never reached the City Hospital and must have died during the hot spell in the last of June, although I could get no history of the case at Bellevue.

This case is strange in the fact that there was no traumatism nor was there any ulcerative process going on in the cornea. There was no staphyloma. Had there been any of these conditions, there would be nothing unusual about the case. The patient had well-marked arteriosclerosis, as might well be expected in a person of her age. It is possible, perhaps, that straining at stool may have ruptured one of the vessels of the eye and produced the hemorrhage, which, as I have already stated, was unusually large.

I have been unable to find any literature on the subject, or to find any colleague who has heard of a similar case.

Brooklyn Hospital Gets $3,000.—The will of Dr. William Augustus Pierrepont of Brooklyn was filed recently. Dr. Pierrepont was unmarried and died on January 6th, a few days after the death of his mother. The Brooklyn Hospital receives $3,000 for the endowment of a bed to be known as the "Dr. Pierrepont Bed."

MEDICAL PROGRESS.

OBSTETRICS AND GYNECOLOGY.

Puerperal Phlebitis in an Unusual Locality; Relapse.—Puerperal phlebitis occurring outside of the uterine veins or the vessels of the lower extremities is comparatively rare. Hence special interest attaches to a case involving the epigastric and internal mammary veins, observed by M. PINATELLE (Gaz. hebd. de Méd. et de Chir., Dec. 19, 1901). The veins of the lower extremities were first attacked about a week after labor, and the phebitis gradually ascended, attacking the vessels of the abdominal wall. The patient was febrile for two months and unable to walk for six months. Eleven years later, no miscarriage, pregnancy or new infection having occurred in the interval, a relapse recurred; the pain and swelling on this occasion were limited to the left abdominal wall, where the thickened, sensitive, cord-like veins could be distinctly palpated. Two years later a third attack of phebitis occurred, this time affecting the right side and embracing the region between the xiphoid appendix and the root of the thigh. There was no sensitiveness, edema or loss of power in the lower extremity.

Lacerations of the Perineum.—A number of essays have been written for the New York Medical Journal (Dec. 28, 1901) upon the causes and methods of preventing this annoying complication, which, if not repaired at once, frequently causes a great deal of misery later. G. B. TWITCHELL says that the vulvar opening is not stretched as by an entering wedge, but by having the lower end pushed away from the upper. That is, if, in the swinging of the head, as it extends, it *slides* on the perineum, the space between the pubes and fourchette will increase; on the other hand, if the head *does not slide* during this swing, the opening will not increase and the perineum will follow the head. The best lubricant to facilitate this sliding is the natural one and hence douches, frequent examinations, etc., are to be avoided. M. A. WALKER urges the importance of emptying the rectum and bladder to give more room, as a preliminary step. During the latter part of the second stage all voluntary effort should be stopped so far as possible by encouragement not to "bear down" and later by chloroform. Too rapid advance may be avoided by pressure with the fingers pointing posteriorly and pressing against the (maternal) posterior segment of the head during each pain. Thus by retarding the advance of the frontal segment there is a tendency to increase flexion and allow the suboccipital region of the head to pass as far as possible underneath the pubes. The shortest diameter of the head thus comes in contact with the vulvar outlet and the head should be slowly extended over the perineum between pains, taking care that the nose and chin are not born with a jerk. J. L. ANDREWS sums up the subject by advising (1) patient and persistent endeavor to bring the longest diameter of the presenting part in relation with the longest diameter of the outlet, and (2) the constant effort to secure perfect dilatation of the soft parts. All writers advise against placing the fingers in the rectum to assist extension on account of the danger of infection, and most of them express themselves as opposed to episiotomy.

Submucous Myomectomy.—The removal of fibroids of the uterus located just beneath the mucous membrane is usually done through the vagina, with or without cutting the neck of the uterus, provided the tumor is not too large. A. RABAGLIATI (Med. Press and Circ., Dec. 11, 1901) encountered a large fibroid which he could not remove except through the abdomen. After exposing the uterus and drawing it up into the wound as far as possible, he opened its anterior wall by a free incision until the mass was reached and shelled out. This left only the mucous membrane separating the wound in the vagina from its cavity. As a preliminary step before making the incision he gently clamped both ligaments to be sure no severe hemorrhage should occur as soon as the deep work was begun. After the clamps were removed no such hemorrhage occurred, but as a precautionary measure their use was wise. The wound of the uterus was then sutured in tiers and the abdominal wound closed without drain in the usual way; a complete uneventful recovery followed. The myoma measured five and one-half by four and one-half inches and consisted chiefly of a mixture of myomatous tissue embedded in fibrous tissue.

Dysmenorrhea.—This most troublesome condition is discussed from the standpoint cause in an exhaustive paper by Dr. MENGE (Centralbl. f. Gynäk., 1901, No. 50). The pain of this condition is very like that of childbirth, as is admitted by all women who have borne children and suffered from dysmenorrhea. The after-pains of childbirth, moreover, bear out the supposition that obstruction in the canal of the uterus is the most fertile cause of the pain. In this case it is the large clots of blood which are the source of the obstruction, although the canal is almost wide open. The degree of the pain depends upon the character of the obstruction and the condition of the central nervous system. If the obstruction is large, then the pain alike in childbirth and in dysmenorrhea is much greater, even with a healthy nervous system. The converse also obtains and we find many women who suffer little pain during childbirth and none during the menstrual flow. On the other hand, there are very many women who have functional neuroses and therefore, although there is little or no obstruction, suffer intense pain under both conditions. Pains of dysmenorrhea are also comparable to those experienced when a foreign body is left in or has grown in the organ. Such are polypi, mucous, fibrous or placental; remains of the decidua; sounds, gauze or pessaries. Here again the disproportion between the canal and the foreign body determines the amount of pain. Dysmenorrhea is also due to an early improper clotting of the menstrual blood, which should be fluid, at least until after it has left the uterus. The highest degree of dysmenorrhea is reached with a healthy nervous system when all the blood of the menses is retained, as is seen in congenital closure of the uterus with the development of a hematoma at the time of puberty. As soon as the blood is evacuated all the pain disappears. It is also seen in occlusion of the internal os, sometimes secondary to operations or to the use of caustics. Removal of the cause cures without treatment of the nervous system. With normal genital organs dysmenorrhea may occur from the presence of mucus in the canal of the cervix. Usually when this is expelled the pain decreases or ceases. Occasionally, however, it continues owing to the disturbance of the nervous system by the pain first experienced. The small narrow canal of the cervix, without disease, in young women and nulliparæ may cause both dysmenorrhea and sterility. Here by mere dilatation, with or without incision, the symptoms usually disappear. Permanent relief is present only after childbirth. Often these patients require, however, long treatment of the nervous system. Inflammatory dysmenorrhea is the last type. This should be treated by removing the cause and always by treating the nervous system, because this is damaged by both conditions. Without doubt the purely nervous

type of dysmenorrhea, namely, that in which the nervous system has been damaged, is the most common of all and accounts for the widespread amount of hysteria and neurasthenia in women. The importance of this condition is usually overlooked by physicians. It, however, demands most careful and patient treatment in the usual ways.

Early Sign of Pregnancy.—The earlier a diagnosis of pregnancy and of the death of the fetus can be made the better. O. SCHAEFER (Centralbl. f. Gynäk., 1901, No. 50) says that careful observations will show in the newly-pregnant woman a temporary pointedness of the features, swelling of the breasts and an unexplainable and obstinate tendency to faint, decrease in the urine, somnolence, forgetfulness and temporary decrease in mental acumen, if the patient is anemic These are the well-known early systemic signs. The new local signs to which he directs attention consist in a characteristic discoloration in stripes, reddish on a livid background, which appear in the neighborhood of the urethra or on the vestibule of the vagina. The stripes run for the most part crosswise or obliquely. So soon as the child within the womb is dead these stripes disappear, especially if the uterus is emptied, even though a packing of gauze be placed within it. The condition is due, therefore, not to the simple hindrance of the blood-flow, but to a vasomotor reaction depending entirely upon the life of the child; as soon as the pains begin with the purpose of emptying the uterus of the dead fetus the stripes disappear. An examination of the blood will also show what the writer terms a resistance of the cells of the blood from the uterus to admixture with various physiologic, pathologic and artificial substances. The most simple and direct method of making this examination is to employ the iodine-potassium-iodide solution of Gram. This mixture makes the so-called resistant blood-cells brown, the less resistant a light yellow and the very feebly resistant almost colorless. As a rule if the woman is healthy, the blood-cells which take a deep stain outnumber the weakest between two and one-half and five to one. The method is not absolutely reliable but is an indication strongly suggestive of pregnancy. Whenever the blood examination is resorted to it will be wise to make a control test of the blood taken from the finger, simply because the blood from the uterus alone may be misleading. Another feature of the blood in early pregnancy is that when the cervix is pricked to draw it down it is rather difficult to stop the hemorrhage.

Twin Births.—Occasionally in pregnancy with twins one child is born and then after a long pause, many hours in duration, the second appears. S. CHOZAN (Centralbl. f. Gynäk., 1901, No. 49) says that when face to face with this condition the practitioner must decide between the policy of patient waiting and active interference. It is not always easy to decide the question. The points upon which a decision may be reached are the general condition of the mother, the reaction of the womb after the first child is born, the presence or absence of active or passive bleeding, and, finally, the state of the unborn child after repeated examinations at short intervals. In general it is best to withhold interference until some definite indications arise.

Spontaneous Facial Paralysis of the Newborn.—The majority of authorities hold that this condition is usually of traumatic origin due to the employment of forceps during parturition. O. MACÉ, (L'Obstétrique, Dec., 1901) claims that there are two varieties of facial paralysis in the newborn—one due to trauma and another which is congenital. The first class results from forceps which produce pressure either directly or indirectly from edema, blood tumors or compression at some portion of the pelvic canal by a tumor. Again, the force of the uterine contractions upon a head passing through a contracted pelvis may be sufficient to cause crushing of the bony canals through which the facial nerves pass out of the interior of the cranium, thereby producing permanent injury to the nerve. Or this same factor may produce cerebral hemorrhage at the point of exit for the nerve. Under the second group he places those caused by anomalies in development of the nerves or their ganglia. Adherence of the amnion is another etiologic factor in causation. Writers have described cases in which there was atrophy of the nerve or complete absence of it on one or on both sides. Congenital facial paralyses are in general unilateral. They are partial or complete and are peripheral or central. Cases of nuclear origin are most interesting. Cabannes has described both unilateral and bilateral forms. In general the prognosis in congenital facial paralysis is good. By the use of the continued electric current in some cases and the interrupted in others, one can hope for recovery if the causation be not an arrested development. The time required is between two or three days or a month.

Surgical Treatment of Dysmenorrhea.—In the treatment of dysmenorrhea the dual relationship between the general health and the generative organs must be constantly kept in mind, says H. D. FRY (Amer. Gyn. and Obst. Jour., Dec., 1901). Impaired general health and normal pelvic organs, stenosis of the cervix, endometritis, displacements of the uterus, diseases of the appendages with impaired general health, or a combination of the foregoing conditions are the usual characteristics found in painful menstruation. In the latter two conditions surgical interference may or may not be indicated. If the pain is acute or is limited to the first day or two, with relief in the intermenstrual period, surgical treatment is not demanded; but if the pain extends over a number of days surgical treatment is indicated. Goodell advocated the method of rapid dilatation and this was supplemented by curettage. Then the application of caustics to the denuded surface with drainage was added and still the results were not satisfactory. Later Dr. Gill Wylie employed a drainage plug held in position by a Smith pessary for six days. The author follows this mode of procedure, but keeps the plug in for from three to six weeks and confines the patient to her bed for two or three weeks. If no discomfort is experienced, the patient is permitted to go about with her plug *in situ* for several weeks longer. The hard rubber drainage tube causes the formation of a cicatricial ring of tissure at the point of constriction which ensures patulency. In a few cases the plug causes pain and must be removed sooner than the specified time. When there are fibroids or displacements or even painful ovaries the author follows out this method of treatment and later performs a second operation to relieve the other existing conditions.

The Angiotribe.—The practical application of the angiotribe will suggest itself to every thoughtful surgeon, says J. N. ELLIS (Amer. Gyn. & Obstet. Jour., Dec., 1901). It is useful whenever it would otherwise be necessary to ligate *en masse* a vascular pedicle, reducing its bulk to the least possible dimensions consistent with safety, and, by the action of the angiotribe alone, or with the aid of a supplementary ligature of fine catgut, assuring perfect primary and permanent hemostasis. The possibility of a secondary hemorrhage with the use of the angiotribe alone is considered by some surgeons, but the author has never seen the accident in his personal experience. Microscopical ex-

amination of the compressed tissue by Thumin shows that the integrity of the compressed tissue is not destroyed, but that it is simply compressed; proving that necrosis and sloughing do not take place, but that a gradual process of revitalization is the result. It is impossible to formulate a fixed rule as to when it is necessary to supplement the action of the angiotribe with the precautionary ligature. This must be determined by judgment, observation and experience. The amount of force and the time of its application depend upon the density of the tissues involved, the size of the pedicle and the object it is desired to attain. The angiotribe is inapplicable to control hemorrhage or secretions or wounds of such friable organs as the liver, spleen and kidney, but its utility in retro- and transperitoneal nephrectomy and in splenectomy is evident. In vaginal hysterectomy angiotripsy is particularly advantageous. In supravaginal hysterectomy it can be used to crush the broad ligaments and also the cervix at the point of amputation. In removal of approximately normal adnexa or excision of small ovarian or intraligamentous cysts it produces absolute hemostasis. It is unnecessary and unjustifiable in appendectomy if either the McBurney or Dawbarn operation can be employed. The use of the angiotribe is by no means limited to operations within the abdominal and pelvic cavities. In thyroidectomy it is of excellent service. It can be employed in the removal of pedunculated keloids and for compression of the spermatic cord in castration. The author uses it to amputate in elephantiasis of the labia, clitoris or scrotum. As a substitute for the pile clamp, in the operation for hemorrhoids, Dr. Robert T. Morris tells the writer that it not only destroys the vessels, but also the nerves, so that the patient is unaware that an operation has been performed. It is also useful in removing portions of the rectum in prolapse or in any of the methods of proctotectomy and proctosigmoidectomy. It is a simple and an excellent means of performing circumcision in infants and in controlling the hemorrhage at the frenum in circumcision of adults.

Surgical Intervention in Dystocia from Fibroids.—The following conclusions are reached by ANDRÉ BOURSIER (Annales de Gyn. et d' Obst., Dec., 1901) in regard to the various operations and indications for operations in this condition: (1) Fibromata cause in many instances vicious fetal positions and form a mechanical obstacle to the downward passage of the fetus. (2) This is more often the case when the fibroma is either at the lower portion of the uterus or at the cervix. (3) If the fibroma is diagnosed it may be removed after or even during labor. (4) Dystocia from causes in fetus or uterus justifies surgical intervention. (5) Fibroma of the vaginal region should be removed by the vaginal route. (6) Those of the abdominal type should be operated upon suprapubically. (7) Symphyseotomy is to be absolutely rejected in this condition. (8) Conservative Cæsarian operation is justifiable in certain exceptional cases. It is a better operation than the complete effacement by myomectomy. (9) The Porro operation must be reserved for certain particular limited cases. (10) Complete hysterectomy is radical and truly curative and is the method of choice to be employed whenever possible, be the child living or dead.

Use of the Uterus in Cystocele Operations.—On account of the unsatisfactory results which follow the various modifications of colporrhaphy, J. BRETTAUER (N. Y. Med. Jour., Jan. 11, 1902) recommends the use of the uterus in increasing the strength of the anterior vaginal wall, an operation which has heretofore been performed a few times. An incision is made through the anterior vaginal wall extending backward from the urethral opening; the parts are separated; the uterus is markedly anteverted and brought down into the wound, thus lying between the anterior vaginal wall and the bladder. It is then stitched in place and a part of the vaginal wall usually resected before it is sewn up. Of course, this operation is suitable only in women beyond the child-bearing period. The results in three cases seem very satisfactory.

Ventrosuspension of the Uterus.—On account of disastrous results which sometimes follow fixation of the uterus to the anterior abdominal wall, especially during pregnancy and labor, numerous methods have been devised to allow a certain degree of mobility and yet suspend the uterus in its normal position. The Alexander operation is difficult, requires considerable training and makes no provision for the bound-down uterus, which is the one usually requiring interference. D. T. GILLIAM (N. Y. Med. Jour., Jan. 4, 1902) has devised an operation which he believes proves efficient. An incision, three inches long, is made in the median line; the adhesions are broken up, and, with the finger behind the broad ligament, the round ligament is caught up at a point an inch and a half from the uterus and a thread passed around it. The other ligament is similarly treated. The skin and subcutaneous tissue are retracted from the fascia and muscular layers of the abdominal wall and a perforation is made through the fascia and muscular layers, beginning half an inch from the wound and passing downward and outward into the peritoneal cavity. Forceps are passed through this opening and by means of the thread the round ligament is drawn out through the perforation and stitched to the fascial layers. The uterus is thus not fixed, but rests easily and naturally against the bladder, and varies in position with the condition of that organ and the rectum. The normal course of a pregnancy is in no way interfered with.

Spurious Abortion.—During the last few years there have been reported three cases which purported to be instances in which, after a few weeks of amenorrhea accompanied by enlargement of the uterus, the formation of the decidual membrane and symptoms of pregnancy, this decidua was thrown off and no ovum was found. In two of these cases an ectopic gestation was suspected and an operation done, but no evidences of any ovum was discovered. It has, therefore, been supposed that these symptoms and signs of pregnancy were not due to the presence of an ovum, but that there was some other stimulating factor. W. E. FOTHERGILL (Med. Chron., Dec., 1901) had the good fortune to see such a case and after a thorough microscopical search a small, shriveled ovum, not more than five or six days old, was found. This had undoubtedly been the exciting cause in the production of the signs of pregnancy, but could be very easily overlooked. It is thought that all the reported cases have been similar ones and that the ovum could be found, perhaps, only after a most diligent search. In order to exclude extrauterine pregnancy it is, however, necessary to be sure that such an ovum is present in the decidual membrane.

SURGERY.

Cases of Rupture of the Spinal Ligaments.—In the long bones oftentimes fractures and luxations will occur before the ligaments rupture. That this is not so generally true in the case of the bones of the vertebral column and their ligaments is the belief of C. A. PAINTER and R. B. OSGOOD (Boston Med. and Surg. Jour., Jan. 2, 1901). These writers present an analysis of all the cases in the literature classified as injuries to the spine accompanied by ruptured ligaments. In addi-

tion they report four cases of injury to the spine in which there was kyphosis without tuberculous or other disease of the vertebræ, in which there were symptoms of pressure on the cord, which symptoms were relieved, entire functional restoration following a few months after treatment with plaster or leather jackets was begun. The force which commonly produces rupture of the spinal ligaments is applied either from above downward upon a flexed vertebral column, or from below upward. In one case muscular exertion alone was responsible for the rupture. This case was examined postmortem, and it was shown that there was no fracture nor dislocation present. The authors believe that nerve-pressure symptoms may occur from a simple flexion of the vertebral column; in their own four cases flexion of the column would bring on pressure symptoms which could be immediately relieved by hyperextension; there was no apparent lateral deviation of the spinous processes and nothing to suggest forward displacement of the vertebræ at the seat of the kyphos. Recovery is promoted by prolonged rest in a position which favors the repair of the ruptured ligaments.

Craniotomy.—A simple, rather rapidly operating instrument for opening the skull has been devised by J. SCHOEMAKER (Centralbl. f. Chir., 1901, No. 50.) The usual four holes are bored after the method of Doyen. Into two opposite holes the instrument is inserted and within a minute or a minute and a half a cut up to about 10 cm. long can be made. The instrument consists in a cutter held in a traveler and kept from twisting by a brace on either side. The traveler has a vertical handle for steadying it, runs along a shaft, and is advanced by a screw propelled by a ratchet and pawl in the right hand while the left grasps the handle. Counterpressure against the advance of the cutter is gained at the other hole where the end of the shaft suitably bent is received. Without chipping or splitting, the cut steadily proceeds with rapidity enough for all practical purposes.

Covering Defects in the Skull.—Absence of the bone-covering of the brain following accident or operation is a serious matter for the patient. For the covering of large defects of the skull through injury or operation after the method of Müller-König, the following rules are emphasized by A. DEHLER (Arch. f. klin. Chir., 1901, B. 65, H. 1.) They must be covered by secondary implantation because the wound must be brought to a condition of absolute asepsis, so that the pus-processes so fatal to life and so damaging to a healing of the bone-flap may be avoided; (2) because the splinters of bone broken out by the injury cannot be replaced evenly and satisfactorily as a rule, at the primary operation; (3) because if the granulations in the neighborhood of the wound have grown upward to a suitable distance, they will much better support and nourish the new bone-flap and fill up the whole cavity; (4) because by a secondary implantation a good opportunity is given the patient to recover from the first operation and gain strength enough to accept the new bone tissue. A further technic is that all scar tissue be removed as fast as possible without damage to the brain over the area of implantation. The margins of the bone defect should be freshened and the flap consisting of periosteum and bone should be somewhat larger than the defect itself. In determining the place of this flap it is necessary to reckon with a later displacement by the contraction of the scars. The larger the flap the greater is the importance of a large artery in its base to secure full nourishment. It is not necessary to have in the base of the flap a thin layer of bone cortex with the periosteum attached. It is worth while to see that between the transplantation of this combined flap and a hairy skin-flap a sufficient time shall intervene so that the former shall be fully in place before it is disturbed at all to accommodate the latter.

Ureteral Anastomosis.—The necessity for this operation arises at unexpected moments during laparotomies by the vaginal and abdominal routes. Every surgeon must be well informed, therefore, as to the various ways of uniting the severed ureter. W. K. TURNER (Annals of Surgery, Dec., 1901) reports a case in which the usual method of making the union was reversed in the following manner: While removing the uterus for complete prolapse of that organ and of the vagina with the bladder, the ureter was divided about two inches from the bladder through having been mistaken for a vein. On investigation the distal portion was found to open in the bladder and urine dripped slowly from the other end. Van Hook's method of union was at once determined upon, but in bringing down the proximal end it was split upward for one inch. Thus, the interval between the two ends and the corresponding difficulty of uniting them were increased. The advisability of opening the abdomen for carrying on the operation was now considered and rejected. Since the upper segment was already split and the vagina already widely open, he decided to reverse the method of Robinson by implanting the lower into the upper end. A curved needle with a ligature was passed through the wall of the lower segment, thence into the canal of the upper portion for an inch above the split and through the wall of the ureter and the surrounding structures on to the peritoneal surface. The needle was then taken off and the suture caught with a pair of forceps; the needle was then threaded on the other end of the suture and the steps were repeated as before. By manipulation and traction the lower end of the severed organ was drawn into the upper, and there tied. Fine sutures now completed the anastomosis and the joint was re-enforced by a covering of peritoneum; the vagina was packed with gauze and the patient put to bed in a very good condition with orders for strict attention to the dressing for leakage. Eight hours after the operation eight ounces of urine were withdrawn by catheter, which suggested that the repaired ureter was doing its duty. One year has elapsed since the operation and the patient is perfectly well.

Thyrotomy for Infraglottic Laryngitis.—A case exhibiting difficult respiration and altered voice from a subglottic growth is reported by G. MASINI (Gazz. degli Osped., Dec. 8, 1901). Laryngoscopic findings were the following: Rima glottidis narrowed to three millimeters and irregular in outline from turgescence of the vocal cords, the latter being red and immobile; arytenoids showed limited motion on inspiration and attempts at phonation; below the cords was seen a pale red papillomatous growth, filling the interligamentous space as far as the posterior third of the aperture between the cords. Other measures for the relief of the patient's respiratory distress having failed, thyrotomy was performed under chloroform, the usual technic of laryngeal surgery being followed. After the cavity of the larynx was opened, a considerable portion of the tumefaction was removed by curettage; induration of the tissues in the intercartilaginous region and the fear of injury to the crico-arytenoid articulation prevented entire removal of the growth. The wound was closed by suturing the thyroid cartilage, a cannula being left in position; the latter was permanently withdrawn on the thirtieth day as the respiratory function was fully reëstablished. The patient has been under observation for nine months, there has been no recurrence of respiratory trouble and the voice has been almost entirely restored, although the laryngeal picture still shows

some deviations from the normal. Unfortunately a microscopical examination of the tissue removed was not made.

Cervical Ribs.—In 1895 Küster collected 139 cases of ribs developing from the transverse processes of the seventh cervical vertebra. Among these cases 28 were diagnosed *intra vitam*, and of the latter number about half gave pronounced clinical symptoms. M. BORCHARDT (Berl. klin. Woch., Dec. 23, 1901) describes four cases of this character recently operated upon at Von Bergmann's clinic. The circulatory disturbances produced by supernumerary ribs are due mainly to the neighborhood of the subclavian vessels. Operation is indicated when a progressive aneurism results, inasmuch as the continued growth of the latter is dangerous to life. In numerous instances syringomyelia is an associated condition. In cases in which the chief symptoms are due to pressure in the brachial plexus and in which electrical treatment fails to give relief, operation may be undertaken with excellent prospects of cure. If, however, in addition to brachial-plexus symptoms, paralysis of the recurrent nerve and widespread disturbance of sensation be present, general disease of the nervous system is to be predicated.

Diagnosis Between Acute Appendicitis and Atypical Typhoid Fever.—Fortunately, operations in the initial stages of typhoid fever are as a rule well borne, and it is the initial stages of atypical cases of typhoid that most frequently suggest appendicitis. When a late perforation in an unrecognized typhoid, manifested by pain, tenderness, rigidity and other symptoms of general peritonitis, is operated upon for supposed appendicular peritonitis, the prognosis is very grave. In acute abdominal lesions, considered from the surgical point of view, four symptoms are of especial weight. These symptoms, writes M. H. RICHARDSON (Boston Med. & Surg. Jour., Jan. 9, 1902) are pain, tenderness, muscular rigidity and fever. The absence of any one of these symptoms throws doubt upon the diagnosis of peritonitis. No lesion of the appendix sufficiently extensive to affect the peritoneum can possibly exist without either pain, tenderness, rigidity or fever. If pain, tenderness and fever are present without rigidity of the overlying muscles, a peritonitis localized about the appendix is at once excluded, though an intra-appendicular lesion may be present. Pain and rigidity without tenderness would throw serious doubt on the diagnosis of appendicitis.. The absence of fever alone, the other three symptoms being present, would form the least doubtful combination, for absence of fever is sometimes conspicuous in really serious local peritoneal infection. The absence of rigidity must put the surgeon on his guard; he must account for the absence of this symptom before he opens the abdomen. In such a case exhaustive inquiry into the history of onset, previous malaise, prevalence of typhoid in the community and history of the pain itself, must be made. Careful examination of the blood is imperative. Without pain at some time in the course of the disease there can be no acute surgical lesion of the abdomen. The absence of rigidity or tenderness in the presence of fever and pain usually signifies typhoid, or simple continued fever. If constitutional signs in a doubtful case are severe, but local ones hard to establish, Richardson would postpone operation; but when the abdominal symptoms—pain, tenderness, rigidity, with or without distention—call loudly for operation, he would open the abdomen in spite of the possibility of typhoid.

X-ray in Bone Diseases.—The important aid which the Roentgen rays afford in the differential diagnosis of osteomyelitis, osseous cysts, osteosarcoma and other osseous lesions is duly emphasized by CARL BECK (Jour. Amer. Med. Assoc., Jan. 4, 1902). Osteomyelitic foci can be distinguished by their light shade in the midst of the dark shadow of the cortex. The regularity of the cortical line and the external proliferations distinguish it from osteosarcoma and the absence of distention from osseous cyst. Necrosis and other later stages of inflammatory processes can be distinctly represented and sequestra also made out. It is somewhat more difficult to diagnose inflammatory processes in the joints. In acute rheumatism and inflammatory processes due to infection the integrity of the articular outlines is well marked, and in the latter case the distention of the joint by serum or pus can be detected. In chronic rheumatic processes the articular bone line appears irregular. In arthritis the contours of the bone epiphyses are irregular and the deposits are recognizable as light shadows of the deformed epiphyses. In tuberculosis of the bones and joints differentiation by the X-ray is readily possible from other lesions which clinically resemble it. The walls of an intra-osseous focus appear thickened, portions are translucent and their contours irregular. The articular outlines of a joint are irregular and appear diffuse, cloudy, and sometimes shaggy. Cheesy foci appear translucent in later stages, the cortex is sometimes destroyed and leaves the impression of having been scooped out with a gouge. In tuberculous coxitis, the upward dislocation of the femur and the separation of its head in the acetabulum can be readily recognized. The only marked sign of tuberculous spondylitis consists sometimes in the presence of an abscess below Poupart's ligament, the nature of which can be interpreted only by the existence of vertebral changes. The skiagraph of a periosteal sarcoma is characteristic, since it shows fine, spiculated trabeculæ that radiate from the surface. In the soft myelogenous variety an absence of osseous tissue is seen, only small fragments being left here and there. The hard myelogenous variety shows more osseous tissue than the former, but its outlines are very irregular. In chronic osteoperiostitis, the walls appear irregular, but the irregularity is one-sided and exteriorly; in tuberculosis the shade would be cloudy or baggy; in osteomyelitis the cortex shows nearly normal outlines. The skiagraphic expression of syphilis is marked in the congenital form by the presence of large ossified areas in the epiphyses that would appear translucent in their normal cartilaginous condition. On the other hand light areas are noted in the diaphyses as an expression of insufficient calcareous deposition. Gummata show regular, light shaded foci, which disappear upon administration of potassium iodide. Osseous cysts may easily, if the same clinical signs are present, be confounded with sarcoma. In cyst, however, the cortex usually appears narrow, well marked, and regular. The fluid center appears translucent and the adjacent epiphyses are normal.

Traumatic Intracranial Lesions.—The difficulty of determining the exact intracranial condition after an injury makes the indications for operations rather indefinite and dependent largely upon the surgeon's diagnostic ability. C. PHELPS (N. Y. Med. Jour., Jan. 11, 1902) believes that even a rational suspicion of the existence of a simple fracture, as in case of a hematoma with a history of considerable violence inflicted upon the head, with or without concurrent symptoms of intracranial lesion, demands explorative incision. Unsuspected osseous depressions and most serious, yet remedial, complications have thus been discovered and relieved. It entails no conceivable danger. If the fissure is found closed, further investigation is not warranted unless symptoms indicate it. An open or comminuted fissure always demands investigation. In dealing with hemorrhages and brain injuries the problem becomes

more difficult. The supradural form of hemorrhage (between the dura and bone) is the one which offers the best prospects for success and fortunately can usually be diagnosed. With or without primary unconsciousness, an interval of consciousness most frequently precedes its later loss. This fact is the most essential point in diagnosis and in conjunction with a subnormal or slightly elevated temperature can hardly be misinterpreted. A man suddenly dazed by a blow or a fall, who goes home thinking the injury is trivial and later develops a progressive stupor and coma, surely has an intracranial hemorrhage and almost as certainly it is of a supradural form. Subdural hemorrhages and brain injuries are less easily diagnosed, and the results of treatment are so uncertain that interference is seldom indicated.

PATHOLOGY AND BACTERIOLOGY.

Reagent for Iodine.—To determine the presence of iodine in the various secretions, G. DENIGES and J. SABRAZES (Münch. med. Woch., Dec. 17, 1901) recommend the following: One gram of starch is mixed with 10 c.c. of cold distilled water; then 40 c.c. of boiling water is added and the whole boiled for from one to two minutes; on cooling, 0.5 gram of nitrite of sodium is incorporated with the mass, which is then brushed on suitable paper. When this is dipped into the liquid to be examined and then touched with a glass rod moistened with 10-per-cent. sulphuric acid it forms a very delicate, stable reagent for iodine.

Pathology of Cholelithiasis.—In an excellent article on the pathological lesions and the determining causes of cholelithiasis A. S. MASCHRE (Cleveland Jour. of Med., Nov., 1901) reviews the literature upon the subject, showing that Naunyn was the first to place the subject on a scientific basis by establishing the fact that cholesterin and bilirubin-calcium are the most important constituents of gall-stones, and, furthermore, that the amount of these stone-forming substances was entirely independent of the general metabolism and diet. Kausch found no increased amount of cholesterin in the bile in any disease except cholelithiasis, and it is now generally accepted that cholesterin is the product of the mucous membrane of the biliary passages. It also results from tissue degeneration elsewhere, but its presence in the bile can be traced to degenerated biliary epithelium. Similarly the lime proportion of the bile has been found to be independent of the diet and proportion of lime salts in the blood, but depends on the production of mucus by the mucosa of the biliary passages. Cholesterin is found only in those ducts which have the same kind of epithelial cells as has the gall-bladder. Thus we see that some pathologic process of the mucosa leading to degeneration of the epithelial cells is the prime factor in causing gall-stones. Stagnation of the bile was thought to be an efficient cause, but it has been found that stagnation alone is not injurious to the mucosa. Normal bile is sterile, but when the flow becomes delayed bacteria are frequently present, especially the bacilli coli and typhosus, and these are often found within the gall-stones. Thus it happens that age, sex, pregnancy, clothing, sedentary life, etc., which usually are considered predisposing factors, serve only to bring out one important fact, that anything that favors stagnation of bile favors the occurrence of lithogenic catarrh. Cholelithiasis is then a local disease not in any way dependent upon constitutional or nutritive disturbances. Cholesterin of gall-stones has never been in solution in the bile, but has been formed from local epithelial degeneration resulting from catarrh. As cause of the catarrh any factor that favors stagnation of the bile and thus renders infection possible is considered the predisposing influence.

Elimination of Toxins in Typhoid Urine.—Observation has shown that the urine is one of the most efficient excretions for the elimination of toxins in typhoid fever. All means, therefore, which increase the urinary toxin output in this disease are of value. L. INGELRANS and M. DEHON (Comptes Soc. Biol., Dec. 6, 1901) have submitted this question to experimental research. They selected for study eight cases of typhoid fever. Four were treated by warm baths, two by cold baths and two were given large quantities of water internally, but no baths or antipyretic treatment of any kind. The urine of these patients was gathered daily and inoculated intravenously into rabbits. Thus its toxic effect was noted. They found that in those treated by warm baths the toxicity of the urine remained stationary or diminished day by day. Those treated by cold baths showed a gradual increase in the amount of toxins present in their urine, except when the temperature was considerably elevated. The urine toxicity showed a notable increase in those to whom abundant amounts of water were administered and the urotoxic coefficients were higher in this class than in either of the other two. It is thus seen that the abundant consumption of water is of great avail in ridding the system of toxins in typhoid fever.

Thyroid Gland in Infectious Diseases.—The study of the histological changes present in the thyroid gland in infectious diseases is of comparatively recent origin. The most recent work upon this subject comes from S. KASHIWAMURA (Virchow's Archiv, B. 166, H. 3). He examined 55 thyroids of which 38 were taken from persons dead of infectious diseases. As a means of comparison 17 were taken from persons in whom death was due to other causes. Of the infectious diseases thus studied 6 were diphtheria, 6 scarlet fever, 5 miliary tuberculosis, 5 measles, 4 fibrinous pneumonia, 3 puerperal fever, 2 typhoid fever, 2 septicemia and 5 pulmonary tuberculosis. Only those thyroids were selected for examination which showed macroscopically no extensive hyperplasia, since in such glands the normal hyperplastic changes might lead to confusion. The connective tissue of the gland is increased in amount in infective diseases; especially is this the case in tuberculosis, typhoid fever and diphtheria. In the majority of infective diseases the interstitial lymph-vessels show an accumulation of colloid material. By the employment of Von Gieson's stain it is possible readily to differentiate this from hyaline degeneration. As such colloid degeneration is found in connection with non-infective processes its appearance here is not characteristic. The gland substance itself is not characteristically altered. Some authors have claimed that the presence of exceedingly small follicles in this gland is peculiar to infective processes. Such is, however, not the case, for, while in many instances these were found, in many others no such condition was observed.

Spirillum and Bacillus of Vincent in Gingivitis.—An unusual case of gingivitis is reported by VERGER and ABADIE (Jour. d. Méd. de Bordeaux, Dec. 15, 1901). The following is the clinical résumé: Patient with no history of syphilis or ingestion of mercury; soreness of gums surrounding lower incisors first noticed; two weeks later grayish-white line at edge of lower gums, the latter being red and swollen; lavage with weak solution of bichloride ordered; about a week later patient awakened in night by hemorrhage from the mouth, about half a pint of blood being lost; the following night a second hemorrhage, but less abundant; pseudomembrane gradually extending about

remaining lower and upper teeth; membrane easily removed, showing deep ulcerations beneath. Microscopical examinations revealed spirillum and the authors call attention to this case as showing the severity of lesions caused by these agents, and also as the only one on record in which the lesions were confined to the gums. Treatment by chlorate of potash was found specific.

Action of Gastric Juice on the Bacillus Tuberculosis.—From time to time since 1883 various observers have investigated the action of the gastric juice upon the bacillus tuberculosis. Most of the work which has been done along this line, however, has been carried on by the employment of an artificial gastric juice and is therefore not entirely conclusive as to the results which occur in man under like conditions. In order definitely to solve this problem G. CARRIÈRE (Comptes Soc. Biol., Dec. 20, 1901) has instituted a series of three experiments. In the first series he employed an artificial gastric juice composed of water, pepsin, hydrochloric acid and sodium chloride. Into this mixture he introduced tubercle bacilli obtained from various sources, as sputum, tuberculous organs and pure laboratory cultures. After various periods of time this inoculated juice was injected into guinea-pigs and the results were noted. He found that up to twelve hours no effect was produced upon the bacilli by their presence in this fluid. After this time they became attenuated but were not killed. The greater the proportion of pepsin and hydrochloric acid in the artificial juice the more marked was the attenuation. In the second series the same technic was instituted, but normal gastric juice from man was used. The same results were obtained as in the first series, but the attenuation was less certain. Sometimes no attenuation was observed even after long contact. In the third series tubercle bacilli were fed to guinea-pigs. These were killed after a varying time and with the gastric contents obtained other guinea-pigs were inoculated. In every case tuberculosis was thus produced more or less rapidly. This work is very conclusive that under normal conditions the gastric juice is without appreciable effect upon the bacillus tuberculosis.

Internal Secretion of the Kidney.—The idea that the kidney possesses an internal secretion was first advanced in 1855 by Claude Bernard. Since that time considerable attention has been paid to the subject and many arguments have been advanced *pro* and *con*. The most recent work comes from ALEX. N. BITZOU (Jour. Phys. et Path. Générale, Nov. 15, 1901). Working upon the assumption that if the kidney produced an internal secretion it should be found most abundantly in the venous blood of that organ, he selected rabbits and under anesthesia, observing all antiseptic precautions, collected the blood from the renal veins. This was then defibrinated and preserved. Rabbits were then subjected to experimental uremia by the means of nephrectomy. Some of these were inoculated with various doses of the renal blood obtained as just described, and others were maintained as controls. He found that those nephrectomized animals which were not thus inoculated in a very short time died of uremia, while in those that were inoculated the uremic symptoms were ameliorated and delayed thereby and life prolonged. Such lived from one to two days longer than the uninoculated. As the result of this work he believes that the kidney produces, as do the liver, pancreas, thyroid and suprarenal glands, an internal secretion, that the venous blood of the kidney is richer in such a secretion than the arterial blood of this organ and that this secretion is of great utility in that it is able to suppress for a certain time the phenomena of experimental uremia.

Action of Gastric Juice upon Cholera Vibrio.—As an aid to the solution of this problem SCHULTZ-SCHULTZENSTEIN (Clblt. f. Bäk., Dec. 11, 1901) reports the following experimental facts. In pure water containing .05 per cent. of acid the cholera vibrio is destroyed in six minutes. Water containing pepsin and traces of acid reduces the vitality of these organisms and produces in them granular formations. Pepsin and hydrochloric acid together kill the vibrio if .019 per cent. of the acid is present. Six hundred cubic centimeters of water taken into a fasting stomach contain in from twelve to fifteen minutes in 75 per cent. of cases an acidity corresponding to .03 per cent. of hydrochloric acid and such water kills cholera vibrio in fifteen minutes. In 25 per cent. of cases the acidity produced is less than this. In one instance in which .0142 per cent. of acid was present the bacilli were not killed in one and one-half hours. Fluids containing albumin or peptone or both require an acidity of .097 to .217 per cent. and one hour's contact is necessary for the death of these organisms.

Pseudodiphtheritic Bacilli.—Much has been written during the past few years with respect to the importance of pseudodiphtheritic bacilli. CH. LESIEUR (Jour. Phys. et Path. Générale, Nov. 15, 1901) reviews the literature upon this subject and also the means for differentiating the true from the pseudodiphtheritic organism. He reports the critical study of thirty apparently pseudodiphtheritic bacilli. Of these 60 per cent. subsequently proved to be true attenuated diphtheritic organisms, 20 per cent. were also probably in this class, 10 per cent. were in all probability of the pseudodiphtheritic variety, and only 10 per cent. were absolutely proven to be of the latter species. As the result of this work he believes that in the practical management of diphtheria from both therapeutic and preventative standpoints the existence of pseudodiphtheritic bacilli may be ignored and that all organisms which give the characteristic staining reaction when grown upon solidified serum at 35° to 37° C. for fifteen to twenty hours should be considered as true diphtheria organisms capable of producing the disease.

Tubercle Bacillus and Associated Micro-organisms.—To determine the influence of associated micro-organisms upon the tubercle bacillus, V. DE CIGNA (Gazz. degli Osped., No. 149, Dec. 15, 1901) placed in the thermostat specimens of sputum containing tubercle bacilli both with and without other bacteria. In each case the specimens were left in the thermostat for fifteen days, daily bacterioscopic examinations being made. In specimens showing absence of organisms other than the tubercle bacillus, or their presence in small numbers, there was rapid and marked increase in the number of Koch's bacilli; such specimens were at no time fetid. Specimens containing associated bacteria in quantity showed a daily decrease, degeneration, and final disappearance of tubercle bacilli with proportionate increase in the number of other organisms. Further experiments suggested that the organism most antagonistic to the specific bacillus and contributing most markedly to its destruction was the bacterium coli. Bacterioscopical and clinical observation has demonstrated that in tuberculous patients implantation of a fetid bronchitis or pulmonary gangrene upon the tuberculous condition has caused a gradual disappearance of bacilli from the sputum, with subsidence or obliteration of clinical symptoms of the original disease. The fact that the fetor of sputum in these conditions is due to protei and bacterium coli suggests the possibility of utilizing such agents or their products as therapeutical remedies. Further, the author believes, with other investigators, that, the sputum being the medium most

conducive to multiplication of the tubercle bacilli, remedies which control excessive secretion tend to check increase in the bacilli; thus, the antitoxic value of serumtherapy is reinforced by its influence over catarrhal processes.

Gonococcus in Blood.—The demonstration of the gonococcus in the blood-stream was a matter of difficulty until recently. A successful attempt is reported by E. UNGER (Deut. med. Woch., Dec. 19, 1901) in a case of gonorrheal urethritis complicated by an arthritis involving the ankle, hip, and wrist joints. Aspirations of blood from the median vein when mixed with bouillon or blood-serum showed on culture colonies of diplococci which decolorized by Gram stain. The author advises three precautions in the use of this method for diagnosis: (1) Use fairly large quantities (5 c.c.) of blood, so as to obtain as many bacteria as possible; (2) dilute the blood considerably, so as to decrease its bactericidal properties; (3) select a fluid culture medium, which permits rapid, unresisted development.

MEDICINE.

Undescribed Symptom of Carcinoma.—The presence of very small angiomata of the skin in cases of carcinoma in various parts of the body has been frequently met with by D. LESER (Münch. med. Woch., Dec. 17, 1901). The changes in the skin consist in bright red or bluish-red areas, varying in size from pin-point to lentil, and slightly elevated above the surface. They are sharply circumscribed, do not disappear on pressure, and occur most frequently on the trunk, rarely on the extremities and almost never on hands and feet. Sometimes they are most frequent in the neighborhood of the tumor and the microscope shows dilated and proliferated capillaries. Of 50 cases of carefully examined, undoubted cases of carcinoma, these angiomata were absent in only one. In normal persons and those afflicted with other diseases they occasionally occur, but then only in advanced age and much fewer in number. The author has had no experience as to their frequency in sarcoma or as to their value in the early diagnosis of carcinoma before the presence of other signs.

Methylene Blue as an Indicator of Renal Function.— Information of value as to the condition of the kidney can be obtained by injecting 5 centigrams of methylene blue subcutaneously and then allowing the patient to urinate at frequent intervals. The kidneys perform their function normally if the excretion begins after one-half hour, reaches its maximum in three or four hours to disappear in from thirty-five to fifty hours. It is not sufficient merely to view the urine through transmitted light; to detect small quantities it must be shaken out with chloroform. K. ASSFALG (Zeitsch. f. klin. Med., Vol. 44, Nos. 3 and 4) has investigated various diseases and finds that in chronic interstitial nephritis the excretion is prolonged sometimes up to nine days; in severe chronic alcoholism the excretion begins late and ceases soon; in uncompensated heart disease there is no change as to time that does not belong to the normal, but, owing to the concentration of the urine, its color soon becomes intense; in bichloride poisoning no aberrations were noted; the same was true of cirrhosis of the liver, while arteriosclerosis and traumatic neuroses gave changes similar to those of interstitial nephritis. For the diagnosis of parenchymatous nephritis the method is inefficient. The exact site of excretion in the kidneys is still a disputed point.

Enlargement of the Hands and Feet.—Several cases of symmetrical enlargement of the hands and feet, depending upon increase in size of the skin, and with this drum-stick deformity of the end-phalanges and nails, intermittent edema, exacerbating pains and tenderness of the nerve-trunks, are described by H. HIRSCHFELD (Zeitsch. f. klin. Med., Vol. 44, Nos. 3 and 4). It was possible in only one case to ascertain the primary pathological lesion in the form of an interstitial neuritis of the larger nerves. The author cannot classify these cases among the *osteo-arthropathie hypertrophiante* of Marie, since the Roentgen rays showed no thickening of the bones, but he does not deny the close association between this and the lesion under discussion, which he names dermatohypertrophia vasomotoria. In all cases described in the article there was present a primary lesion accompanied by disintegration of tissue. The casual connection between this and the hypertrophy, however, remained obscure.

Typhoid Spine.—The history of an interesting case is contributed to the literature of this subject by W. J. TAYLOR (Phila. Med. Jour., Dec. 28, 1901). Since the appearance of Gibney's original paper in which the "typhoid spine" is described as a perispondylitis, various opinions have been advanced as to its true nature. Three conditions may arise after typhoid referable to the spine: First, the true perispondylitis of Gibney; second, a painful condition of the muscles due to strain or injury; third, the hypersensitive neurasthenic spine. Although most authors do not recognize these distinctions and think that they all border on neurasthenia, the writer believes that in certain cases there is a definite well-pronounced pathological condition involving the periosteum, ligaments, and deep fascia of the spine—a distinct surgical sequel of typhoid fever. It is recognized that the typhoid bacillus may cause a periostitis which resolves without suppuration, although the latter often occurs. As this has been observed to occur in the tibia, why may it not occur in the spine? In the case cited by the author, an adult patient had an ordinary attack of typhoid lasting nine weeks. A few days after getting up the heavy dull pains in the back began. Examination showed a slight prominence of the spine to the right of the sacrum and in the lumbar region, with numbness extending along the right thigh. Patient was kept in bed for nearly four months on ordinary tonic treatment. Improvement took place rapidly and three months later the spine was perfectly flexible and the thickening had disappeared.

Clinical Import of Arteriosclerosis.—In a paper dealing with abnormal conditions of the viscera depending upon arteriosclerosis, J. G. URUENA (Gac. Med. d. Mexico, Dec. 15, 1901) calls attention to the importance of examining the arterial condition, especially in patients presenting cardiac symptoms, as the heart stimulants which might be valuable in valvular disease would be of the greatest disadvantage to the patient with inelastic arterial walls. The author urges the employment of the classical remedies for this condition, *i.e.*, potassium iodide and nitroglycerin; the former administered for twenty days by the mouth in 50-centigram doses, the latter ten days in 3-minim doses. With systematic perseverance in this method of treatment, cerebral distress, cardiac palpitations, and murmurs have subsided when due to peripheral resistance from arteriosclerosis.

Traumatic Apnea.—Traumatic apnea is a condition rarely seen in the living. In a case reported by H. L. BURRELL and L. R. G. CRANDON (Boston Med. & Surg. Jour., Jan. 2, 1901) the patient sustained a crushing injury to the chest, which was held by antero-

posterior compression between an electric car and a door-post for fully three minutes; on the removal of the car he fell unconscious. Admitted to the hospital an hour later, he was still unconscious; pulse 100, weak but regular; respirations 30, shallow. Several ribs were fractured and there was an area of subcutaneous emphysema. A striking feature was the condition of the skin, which, from the third ribs upward over the neck and face, presented a dusky, bluish, mottled appearance. Cyanosis was suspected, but was not the cause, inasmuch as the color was not general over the body, as it did not disappear on pressing the skin, and as it persisted after the patient's general condition improved. Eight days after the accident the blue color began to fade. On his admission to the hospital the patient was in a condition of extreme shock and was stimulated by nitroglycerin, atropine and strychnine, with ice-cap to the head and warmth to the body. Ollivier's theory is that the skin appearance seen in these cases is due to stasis of carbonized blood in dilated and temporarily paralyzed capillaries. History of compression of the chest, evidence of such compression (broken ribs, contusions, etc.), with absence of respiration, unconsciousness and apparent death, with the localized coloration already described, are important for diagnosis. If the patient is seen directly after the injury artificial respiration must be begun at once; the secondary or late treatment is to combat shock in the manner described above.

The Pathogenesis of Complications of Vincent's Angina.—A variety of morbid conditions secondary to ulcero-membranous lesions of the mouth, due to the bacillus of Vincent, have been studied by Simonin (Gaz. hebd. de Méd. et de Chir., Dec. 19, 1901). These conditions may be cutaneous (polymorphous eruptions, purpura hemorrhagica) or may involve serous membranes (arthralgia, pleurisy) or may affect the great vital organs (bronchopneumonia, nephritis, myocarditis). These various complications appear to be due to the common pyogenic bacteria, principally the streptococcus. The associated bacteria of Vincent (fusiform and spirillum) merely produce the local ulcer which furnishes the port of entry to secondary infection; inoculation of animals with this group proves its inability to generalize itself in the body. The tongue and the mouth, presumably on account of their relatively poor lymphatic defense, are especially dangerous sites of ulceration from the standpoint of secondary infection; ulceration of the tonsils is less dangerous. The intensity of the secondary infection is often so great as to lead the clinician to neglect the primitive lesion. It is essential to promote cicatrization of the primary ulcer; for this purpose iodine, peroxide of hydrogen, methylene blue and silver nitrate are recommended.

Method for Determining Pyloric Insufficiency.—It is well known that the usual methods for determining insufficiency of the pyloric end of the stomach are either impractical or inefficient. C. B. Queirolo (Klin.-therap. Woch., Dec. 8, 1901) recommends that a double sound be introduced into the stomach, one end of which has connected with it a small balloon, while the other permits it to fill with air and also records upon a drum any changes in the pressure within the bladder. If, on introducing the balloon and moderately distending it with air, when in the stomach, light percussion be performed over the gastric area, moderate excursions will be recorded upon the drum. If, however, the normal tone of the pylorus is absent, the endogastric pressure will not be increased, since the distention of the balloon will at once be followed by an escape of the gas normally present into the duodenum, so that even strong percussion will give a straight line instead of a number of curves upon the registering instrument.

Symptomatology and Therapy of Chronic Emphysema.—Cases of acute emphysema with sudden increase in the rapidity of the heart's action have been described by Tuczek and others as a neurosis of the vagus. The condition is apparently one of stimulation of certain fibers of the vagus occurring simultaneously with paralysis of other fibers of the same nerve. Attention is now directed by G. Zuelzer (Berl. klin. Woch., Dec. 23, 1901) to a series of cases in which emphysema was associated with slowing of the pulse; in the interpretation of these cases the writer assumes that the pulmonary and cardiac fibers of the vagus are here both in a condition of irritation. The patients were nearly all male adults, whose ages ranged from eighteen to forty-five years. They complained of a sense of oppression in the chest. Shortness of breath followed physical exertion so much that it interfered with occupations demanding such exertion. Cough and expectoration were absent. Cardiac auscultation was negative; percussion showed a concealment of the normal area of cardiac dulness, due to the extension of pulmonary resonance. The frequency of the pulse in the several cases was from 42 to 64 a minute. Partly because of the results of experiments on animals, and partly because in the cases clinically observed pressure over the vagus at the border of the sternocleidomastoid caused exquisite pain, the author regards these cases as primarily instances of vagus neurosis. This theory is supported by results of the administration of atropine. Zuelzer states that after giving 1 milligram of atropine subcutaneously he noticed within from 10 to 15 minutes a retraction of the lower border of the lung and a marked increase in pulse frequency. The sense of oppression in the chest disappeared at once, and after atropine had been given by mouth once a day for eight or ten days the sensitiveness to pressure over the pneumogastric also vanished.

Paratyphus.—Now that the Gruber-Widal reaction in typhoid fever has come to be a generally tested and accepted symptom of the disease, the significance of a certain small residue of cases in which the reaction fails to occur has aroused a great deal of curiosity. The literature bearing upon this subject has been ably summarized in a recent article entitled "Paratyphus" by Meltzer (N. Y. Med. Monatschrft., Dec., 1901). Within the past two years more than a dozen cases have been described in which the clinical diagnosis of typhoid fever was not confirmed by the agglutination test with the Eberth bacillus, but in which the sera reacted promptly to certain other bacteria which could be isolated from the blood or from the excrements. The first case was described by Gwyn of Johns Hopkins in 1898; then followed six from a single epidemic in Hamburg in the same year, and eight from the epidemic of 1901 in Bremen. In all there were headache, prostration, continuous fever, slow pulse, enlarged spleen, roseola, and the diazo-reaction, epistaxis, intestinal hemorrhage, delirium, slight pulmonary affections, and post-typhoidal osteomyelitis occasionally occurred. In short, the cases were clinically typical typhoids. All but three of the cases ran a course somewhat milder than the ordinary typhoid. As none of them were fatal, there is no pathological anatomy. The Widal reaction was absent in all of them. In the case of Gwyn and in the eight cases of Schottmueller in Hamburg bacteria which were agglutinated by the sera of the patients even in high dilution were isolated from the blood. In Kurth's cases from Bremen the bacteria were found in the stools, and were likewise agglutinated. It is extremely important that both in the Hamburg and in

the Bremen epidemic, every case of "typhoid" which failed to give a positive Widal reaction yielded a specific organism which reacted to the serum test with the blood of the individual in question. All the micro-organisms thus isolated are very similar in character, and belong to the so-called colon-typhus group. They are more or less motile, have flagella, and do not liquefy gelatin; from the colon bacillus they are distinguished by the fact that they do not coagulate milk, do not ferment lactose, and do not form indol; from the typhoid bacillus, they differ in producing gases, in fermenting glucose, and in alkalinizing the media. Other pathogenic bacteria of the same group are the bacillus of hog-pest and of epidemic dysentery. Meltzer believes that the results above summarized are universally applicable. He holds that only such cases as give a positive Widal reaction are to be considered as typhoid fever. All the other cases clinically resembling typhoid that fail to give the reaction are caused not by the bacillus of Eberth, but by certain other forms which belong to the same general group. These cases constitute from .5 to 5 per cent. of the cases of "typhoid," according to the varying statistics of different pathologists. They compose a group which he would designate as paratyphus.

Gastric Neurasthenia.—If there is any branch of medicine in which the physician may entertain original notions upon symptomatology and treatment, without the fear of conflicting with an established and definite code, it is the field of functional diseases. Of this privilege DR. HERSCHELL (Edin. Med. Jour., Jan., 1902) has liberally availed himself. He accepts the broad general subdivision into neuroses of sensation, of motility, and of secretion. He is convinced, however, that the importance of the secretory neuroses has been enormously overestimated. With the exception of occasional and unimportant departures, he has found that the composition of the gastric juice is practically normal in all cases of nervous dyspepsia. The neuroses of motility, on the other hand, are of the first importance, and of these the myasthenic forms are the most frequently met with. There are three stages of muscular inactivity of the stomach. In the first, clapotement is obtainable, but the persistaltic activity is sufficient to empty the stomach before the next meal. In the second, the stomach cannot empty itself before the next meal, but does so during the night. In the third, or stage of atonic dilatation, the stomach does not empty itself during the night, and thus always contains food residues. The most important of the sensory neuroses is hyperesthesia, which gives rise to pain and tenderness. The symptomatology of the gastric neuroses corresponds to the above conception of their nature. Succussion, gastroptosis, the presence or absence of food residues after varying intervals of time, are the chief indications of disease. Painful spots may be present. No diagnostic information is to be obtained by the chemical examination of the gastric juices. The special treatment must first obviate any sources of irritation of the gastro-intestinal tract. All dental defects are to be remedied, and chronic fecal retention is to be combated by colon irrigations. The dietary indication is primarily to offset the myasthenia. This is done by ordering small and frequent meals, say five or six during the waking day. The nature of the food is determined by the percentage of hydrochloric acid in the secretions. If there is hyperchlorhydria, he gives foods which, while having a high combining value with the acid, tend to stimulate the secretion of it in the least degree, namely, sweetbreads, brains, oysters, egg-albumin, plasmon, milk. In combating constipation, it is to be kept in mind that this is generally of the spastic type so that the usual stimulants are contra-indicated; Fleiner's injections of warm olive oil at bed-time are recommended. As regards drug treatment, the author believes that the only medication is nitrate of silver in doses of ¼ grain, in palatinoid form, three times a day, or quinine bisulphate in doses of ¼ grain. Upon the physical means of restoring tone to the system the author lays very great stress. Static electricity is to be used in cases in which a general sedative tonic is indicated. In cases in which stimulation is needed, the "sinusoidal bath" is highly lauded and thoroughly explained. Finally, the author makes frequent use of Einhorn's intragastric spray apparatus in cases demanding local treatment of the stomach, upon the theory that it enables one to apply a very small amount of a concentrated solution over a large area of stomach; in other words, to get the direct without the poisonous effects of the drug.

Cocaine Habit.—The effects of cocaine alone are so intense and exhilarating that the person addicted to the habit soon takes whisky or morphine to counteract the effects which would otherwise probably end in acute mania. E. H. MARTIN (Med. Times, Jan., 1902) says that the cases of cocaine and morphine habit are generally among white people, while the combined use of cocaine and whisky appears more frequently among the blacks. The latter two drugs seem to smother all moral sensibilities. Insomnia and anorexia are prominent symptoms and lead to more whisky. The action on the genitals is peculiar. Whether the drug is excreted in the urine, causing anesthesia of the urethra and glans, or whether the sexual centers in the brain are affected is not known, but cocaine always causes the penis to become shrunken and bloodless. Where morphine also is taken the desire is destroyed, but cocaine and whisky markedly stimulate the sexual appetite, erection being, however, impossible, and sexual perversion frequently results. In regard to treatment, the cocaine habit is similar to the whisky habit and can be stopped if the patient has any will power left. A few days' bracing with strychnine is all that is usually necessary, but it sometimes happens that there is great difficulty in giving the victim enough will power. The great increase in the use of coca and coca-cola will undoubtedly lead to there being as many users of these drinks as there are now of coffee, and the effect which the continued use of small doses of cocaine has will probably be more fully understood.

NEUROLOGY AND PSYCHIATRY.

The Bladder in Syringomyelia.—The great variety and confusing diversity in the symptoms of this nervous disease make it a matter of great importance to settle such points as its relation to the bladder. J. ALBARRAN and G. GUILLAIN (La Sem Méd., Dec. 4, 1901) have observed in cases of syringomyelia severe bladder troubles, with pain, blood in the urine and retention. Such have caused them to examine more minutely patients of this class for latent and obscure bladder troubles, when no particular subjective symptoms directed attention to that organ. The first series of persons examined was four. Three of them had latent retention, respectively of fifty, eighty and one hundred and twenty-five grams of urine. The fourth had no retention. In another series of six patients, three had latent retention, one had cystitis with multiple ulcerations of the bladder, incomplete retention and a secondary formation of irregularities in the mucous membrane, and another had total retention with widespread, discrete ulcers. Only one of the patients had a normal bladder. It is therefore apparent that contrary to the classical opinion, symptoms proceeding from the bladder are common in syringomyelia. In some subjects these

troubles are latent, with full or incomplete retention of aseptic urine; but this very state creates a soil favorable for the development of infections of the bladder. Therefore such symptoms break out suddenly as soon as these infections have reached a certain degree or as soon as retention itself causes them mechanically. Morover, they have found lesions of the bladder which present a number of peculiarities far removed from the lesions of ordinary cystitis and similar to those found in chronic retention of the urine. The multiple small ulcers and the large extensive discrete ulcers of the mucous membrane and the perforations of the bladder are the final degrees of those lesions, which should be regarded as taking their origin in trophic changes due to nerve damage and springing from trouble in the spinal cord due to the syringomyelia. The trophic alterations in this disease are very frequent and really determine the classic symptoms of it. Therefore, it is not surprising that they should in certain cases affect the bladder also. In syringomyelia the ordinary difficulty of retention of urine, either aseptic or infected, develops really on a special trophic soil, which in itself should be made part of the pathogenic elements in all the lesions which one observes. Changes in the contractility of the bladder-wall have been proven. Death may follow ulcers of the mucous membrane of the bladder. The final conclusion is that one should examine in a systematic manner the bladder of all patients suffering from this disease, and as soon as any urinary troubles appear should give them careful and persistent treatment in order to obviate the later and fatal stages.

Diphtheritic Paralysis.—The causes of paralysis in diphtheria have been made the subject of a fairly thorough pathological investigation by Foulerton and Thomson (Edin. Med. Jour., Jan., 1902). They studied the nervous system in nine guinea-pigs which had been injected with filtered diphtheria broth in varying quantities, and also in a number of children who died of the disease. They come to the conclusion that the paralyses may be either central or peripheral in origin. In the former case, the anterior horn cell first becomes the seat of degenerative changes, as evidenced by abnormal staining reactions, while the nerve-fiber is still normal in appearance. A secondary descending atrophy of the nerve, however, follows upon the disease of the central cell. In the latter, or peripheral type, of which the common palate paralysis is an example, the muscles paralyzed are those in connection with peripheral nerve fibers which come into close relation with the seat of toxin-formation in the throat and nasopharynx. The central paralyses are toxemic in origin; the peripheral are due to local and direct irritation. The latter have, of course, the better prognosis.

Aphasia During Convalescence after Evacuation of Brain Abscess.—Since the publication of Macewen's work the subject of otitic brain abscess has received less attention from the neurological than from the otological point of view. Such evidence as is afforded by the reports of the cases of Muller, Kühn, Koe, Burnett, Steinburger and Moss points toward impaired function of the auditory word center as a cause of the resulting aphasia. G. L. Walton (Boston Med. & Surg. Jour., Dec. 26, 1901) made a study of Dr. Jack's patient with a view to determining the variety of aphasia present. The details of this examination bear marked resemblance to those in the case of Marie and Sainton, in which autopsy confirmed the localization in the temporal region. The details of the examination conducted by Walton cannot be reproduced here, but it may be said that the case corroborates the views of Broca and Trousseau, who first maintained that there is no writing center in the sense of a center in which are stored up the kinesthetic memories of written words and capable of stimulation independently of Broca's convolution. The inability to write in this case was absolutely coincident with the inability to talk. When the auditory center either failed to recall the memory of the sound of the word, or, if remembered, failed to convey the stimulus properly to the kinesthetic speech center, it failed also to communicate it to the center for the movements of the hand. That the centers and fibers affected were not destroyed is shown by the complete recovery.

Angioneurotic Edema.—This condition, known also as Quincke's disease, is a neurosis of the vasodilators characterized by tumefaction in different parts of the body, affecting the skin and subcutaneous tissues, rarely the mucous membranes, says P. C. Madinos (Gazz. degli Osped., No. 149, Dec. 15, 1901). Little is known of its pathogenesis; all observers of the phenomenon have agreed that the nervous system is concerned in it, Richel holding that it is of central origin, Quincke that it is due to the peripheral nerves. Heredity seems to have some influence, Osler noting its appearance in five successive generations. The author has found a certain connection between the affection and a tuberculous family history. Four cases are cited; the most typical one is given in detail: Young woman, about twenty-five years of age; edema appeared in some part of body two or three days before the menstrual period, spreading from original point, or subsiding there, to appear in other parts successively; feeling of tension in the skin and slight pain on pressure; swelling rather well defined, pale red, pitting when pressed with finger; local temperature elevated. This condition continued for about ten days, then subsided, to reappear upon the approach of the next menstrual period. Treatment with bromides, valerian, and ergotin having failed, recourse was had to faradic electricity, treatment being administered daily for from ten to fifteen minutes. The positive pole was applied to the side of the neck in the course of the sympathetic, the negative to the affected part. After thirty days there was marked improvement and two months' treatment effected a complete cure.

Specific and Non-Specific Lesions of the Brain.—The lesions of the brain that may result directly or indirectly from syphilis can be divided into three classes: (1) those that are caused by the syphilitic poison and by nothing else; (2) those that may have a specific or a non-specific origin; (3) the non-specific lesions that occur as indirect results of the syphilitic virus. J. T. Eskridge (Jour. Amer. Med. Assoc., Jan. 4, 1902) calls attention to the importance of distinguishing between the specific and non-specific lesions, as only the former are especially amenable to antisyphilitic treatment, while the numerous injuries caused by the presence of syphilitic lesions or the degenerations resulting from toxemic or other blood states which may result from syphilis, are in no way specific in character and do not yield to this form of treatment. While gummata are the specific lesions, these by their presence in lessening intracranial space, by their irritating effects, by encroaching on and injuring adjacent structures, produce intracranial lesions that are in no way specific in character.

Cause of Narcolepsy.—Pathological somnolence has usually come under the observation of a neurologist, but, as the prime inducer of this diseased condition probably does not arise within the brain, the general physician should be more interested, and an endeavor made to determine the true etiological factors. H. Stern (Med. Rec., Jan. 11, 1902) describes a case which has been under his care for some time. A car con-

ductor, aged thirty-five, of good habits and no important family history, had for months been seized each day with an almost irresistible desire to sleep, the attack coming on regularly about ten o'clock in the morning and lasting till three in the afternoon. There was free perspiration at all times and especially just before the attack. Physical and clinical examinations carefully made several times were negative except for a somewhat dilated stomach and hyperchlorhydria, high urinary density and acidity, with urinary chlorides greatly in excess. There were a diminished blood alkalescence and a low urinary toxicity both before and after the attack. Variations in diet and medication had no effect on the condition. Analyses showed that the patient egested in twenty-four hours about as much chlorides in his urine as he had ingested in the milk which formed his entire diet. Since he has hyperchlohydria and perspires very freely, especially just before the attack, it follows that for certain periods of the day the output of chlorides must exceed the supply and there exists a deficiency in the blood. Since vital processes are largely dependent upon the osmotic tension of the blood and since chlorides appear to play the most important rôle in the osmotic tension of the body fluids the depression of the nerve centers in the case reported seems to be due to the diminution of chlorides in the blood.

HYGIENE.

The Destruction of Rats by Bacterial Agencies.—The significance of these rodents as a factor in spreading the bubonic plague has led to several methods directed toward their extermination. A specific pathogenic bacillus has been described by DANYSZ, and used by him with favorable practical effect. Another series of trials has been made and new statistics collected by R. ABEL (Deut. med. Woch., Dec. 12, 1901). In his laboratory experiments the rats were fed with the pure culture and died in from six to twelve days. The livers and spleens of these animals were again fed to others; the latter promptly succumbed. This method was continued through six generations. Experiments tried outside of the laboratory varied as to the apparent results. In all cases but few dead bodies were found, this being probably due to the well-known natural aversion to dangerous localities which these rodents possess. Certain much frequented resorts were entirely deserted for several years. Experiments on ships were very unfavorable. It seemed necessary in all instances to introduce large amounts of the culture. The chief indication in future investigations will be to devise some more practical and effective method of administration.

Hydrocyanic-Acid Gas as a Disinfecting Agent.—Several experiments have recently been made by J. S. FULTON and W. R. STOKES (Maryland Med. Jour., Dec., 1901) in the endeavor to show the efficacy of hydrocyanic-acid gas as a germicide; but since the cost of room-disinfection with this gas is about four times that of formaldehyde disinfection, since the gas is more dangerous than formaldehyde, and since the only advantage in the use of hydrocyanic acid is lessened risk of fire, these observations may be considered as being more interesting than valuable. In the treatment of various parasitic diseases of plants this gas has been successfully used by inexpert persons since 1897. A convenient apparatus was arranged by which the gas was not liberated for a few seconds after being started, thus allowing one time to leave and close the room. Various kinds of insects, rats, mice and guinea-pigs were experimented upon and all died within a few minutes. Formaldehyde has been proven to be ineffectual in killing vermin of ships and mosquitoes conveying yellow fever. Sulphur dioxide is here more efficacious and it is for this purpose that hydrocyanic-acid gas may be found most useful. With ordinary care there is slight danger to human life, as the gas can easily be detected and avoided. It has no effect upon foodstuffs and in no way injures furniture, paintings or merchandise.

Bacterioscopical Versus Chemical Examination of Water.—With the effluvium of filth which follows the oil-like spread of mankind over the earth's surface, there arises with rapidly-increasing import the question to drink, or not to drink, of a given crystal water. The chemists have been having their own way in deciding this point, perhaps because there were, until now, easier and more fruitful fields for the bacteriologist to pasture in, but, if the conclusions of A. C. HOUSTON (Brit. Med. Jour., Dec. 21, 1901) are consulted, it appears that the retort and the flame will soon have to give way to the culture and the incubator. It will be seen that the very essence of this able paper is this: The author shows that the pregnant question to be answered is *not* whether certain pathogenic forms are present, but what is their relative abundance? In conclusion, he makes the following statements: (1) From the public health point of view it is the adventitious and perhaps dangerous bacteria, rather than those peculiar to water, which demand attention. (2) As sewage is the most common and dangerous source of the pollution of potable water, further knowledge of the bacteria characteristic of sewage is required. (3) Bacteriologists have hitherto almost entirely neglected the question of the relative abundance of micro-organisms of different sorts in pure and impure substances; for example, water as compared with sewage, virgin soils with polluted and cultivated soils, etc. (4) Attention to this question of relative abundance has a most important bearing on the bacterioscopical analysis of potable waters from a public health point of view, because it shows that a biological distinction between pure and impure substances (for example, water and sewage) is so great as to be almost inconceivable, so great as to render the adoption of rigid and stringent bacteriological standards unnecessary and inadvisable, and so great, also, as to allow the bacteriologist to detect in a water the presence of objectionable polluting material so small as to be far beyond the reach of chemical analysis. (5) Streptococci are absent from 10 c.cm. (or more), bacilli coli from 1, 10, it may be 100 c.cm. (or more) and bacilli enteritidis sporogenes from 100 to 500 c.cm. (or more) of pure waters; that is, these microbes are altogether absent, or relatively so, from pure waters. (6) These three germs are commonly present in $^1/_{1000}$ c.cm. $^1/_{100000}$ c.cm. and in $^1/_{100}$ to $^1/_{1000}$ c.cm. respectively of crude sewage, that is, these microbes are present in crude sewage in great abundance. (7) It is evident from these figures that there are tests in the bacterioscopical examination of water which far surpass in delicacy any known to the chemist. (8) A stage may be reached in the pollution of water with sewage when the contaminating material is so small in relation to the bulk of water as to be inappreciable by chemical means, yet yielding to bacteriological tests unequivocal evidence of gross pollution with germs of intestinal origin. (9) The presence of streptococci is to be thought of as indicating extremely recent, and bacilli coli less recent though still not remote pollution of animal sort, but the presence of bacilli enteritidis sporogenes cannot be considered to afford evidence of pollution bearing a necessary relation to the recent evacuation of animals. (10) Organic matter *per se* is, so far as is known,

harmless; it is the bacteria apt to be associated with the organic matter that constitute the element of danger. (11) It is not necessary to demonstrate in a polluted water supply the presence of definitely pathogenic microbes to prove that there is danger in drinking such water. (12) It is sufficient to show that microbes of intestinal origin are present in a water to condemn it. (13) Valuable as the chemical analysis of a water undoubtedly is, it should in the future occupy a secondary position, and the bacteriological examination should take its place in judging our water supplies.

THERAPEUTIC HINTS.

Resorcin Poisoning.—A case of this kind in an infant five days old is reported by A. CAILLÉ (Pediatrics, Dec. 15, 1901). Resorcin, gm. 0.015 (gr. ¼) every four hours, was ordered, and after the sixth dose the child became cyanotic, pulseless, cold and clammy, and the urine voided before collapse set in had a smoky color. The child was given a hot bath (110° F.) every two hours and kept warm by hot-water packs; the bowels were flushed with a very warm saline solution every three hours, and warm sweetened tea was given by spoon frequently. As soon as the child was out of collapse it was put to the breast, and in a few days its recovery was complete.

Scarlatinal Nephritis.—The patient should be kept in bed on fluid diet, wearing flannel next to the skin. The flow of urine may be increased by plain or carbonated water with bitartrate of potassium or other saline. Prolonged sweating, brisk purging, etc., should not be practised together, but alternately. If oliguria is pronounced or uremia threatening, normal salt solution at 105° to 110° F. may be injected by rectum. This dilutes the toxins and favors their elimination, and lessens the vasomotor constriction. Digitalis ought not to be employed. Calomel, gm. 0.003-0.006 (gr. 1/20-1/10), given every hour, is diuretic, laxative, sedative to the stomach, and reduces arterial tension. Strychnine, dry-cupping for dyspnea, and, if convulsions occur, chloral, hot-packs, and salt water irrigations may be employed. In coma, sodium caffeine benzoate, subcutaneously, braces up the heart, rouses from stupor and starts diuresis. Renal hemorrhages are best treated by hot applications over the loins, mustard plasters and absolute rest. Suprarenal may be tried. Only small quantities of liquid food at frequent intervals should be taken, such as broths, clear soups, equal parts of milk and oatmeal water, etc. In general alcohol is contra-indicated, but cold champagne, c.c. 4.0 (℥i), with ice, every ten to thirty minutes, may be given for frequent vomiting and dry tongue. When edema is marked, dyspnea excessive or pulmonary edema impending, hot packs or hot-air baths may be used. The danger of nephritis is greatest during desquamation. During convalescence, the patient must be kept in bed, or in the house, avoiding exposure or too great muscular activity. The anemia requires iron.—F. HUBER in Pediatrics, Dec. 15, 1901.

Follicular Conjunctivitis.—Mild cases may be cured by rubbing the everted lids with copper sulphate or alum and washing the excess off with sterile water. This may be done two or three times a week, in the interval a solution of zinc sulphate, 0.2-0.4 per cent. (gr. i-ij to ℥i) being instilled three times a day. But operative procedure is more rapid and very effective. With the usual aseptic precautions, and having applied cocaine, pass one blade of Knapp's roller forceps, or Gifford's forceps, well back into the conjunctival cul-de-sac, and the other over the everted conjunctiva, and with firm pressure pull from the eye. This breaks down and squeezes out the follicles. In the retrotarsal fold and near the canthi are points which cannot be reached by the Knapp forceps, and the Gifford instrument is better. After this procedure, mop the lids with bichloride, 1:500, washing off the excess with boric-acid solution or sterile water. Repeat every one or two days, using the zinc sulphate solution from one to three times a day.—J. W. BULLARD in Western Medical Review.

Pneumonia in Children.—If there is much pain at the onset it may be relieved by mustard paste, but later in the disease G. GROTHAN (Western Med. Review, Oct. 15, 1901) prefers to apply to the chest once or twice a day, a flannel saturated with equal parts of lard and turpentine. Over this should be placed a cotton-jacket covered with oiled silk. Flaxseed poultices should not be used. During the early part of the disease but a small quantity of food, if any, should be given, and throughout the disease little food and more water are desirable. The main indication for treatment in ordinary cases is to clean out the bowels and maintain excretions. Hyperpyrexia is treated by cold to the head and cold sponging. The author condemns coal-tar products as a "class" of pernicious drugs. In a severe case calomel may be given, with an intestinal antiseptic such as guaiacol carbonate; later, salicylate of sodium every two hours and the aromatic fluid extract of cascara. The bowels should move at least every twelve hours and if sluggish may be stimulated by normal salt enemata. The kidneys may be kept working by liquor ammonii acetatis, slightly alkaline, made fresh daily and administered every two hours. Strychnine sulphate, gm. 0.0002 (gr. 1/300), every three or four hours for a one-year-old child, should be given throughout. Sudden general collapse may be combated by strychnine and nitroglycerin hypodermically. The hot mustard bath, begun at 100° F. and raised to 110° F., may be used for ten minutes for cardiac or respiratory failure with cyanosis, cold surface, rapid pulse and respiration and extreme nervousness. Cold, or bromide and chloral, will combat nervous irritability and sleeplessness. Codeine sulphate may be given guardedly for pain and cough.

Psoriasis.—In certain cases of this affection, M. BALZAR (Revue de Thérapeutique, Nov. 15, 1901) advises a warm bath every day or every two days, in which is placed

℞ Oil of cade..... 45.0 (℥iss)
Fluid extract of quillaya, c.c. 20.0 (℥v)
Yolk of one egg.
Water to make.....c.c. 240.0 (℥viij)

Make emulsion and mix with a pail of water and then add to the bath.

Recurring Gonorrhea.—The internal administration of drugs is of little or no use, urethral irrigation having the greatest value. A quart of warm solution is flushed through the urethra once daily, the formula being:

℞ Zinci sulph.
Alum, aa..... 0.06 (gr. i)
Acidi carbol..... 0.03 (gr. ss)
Aquæ, q.s. ad.....c.c. 1000.0 (Oij)

Twice daily give an ordinary urethral injection of protargol, gm. 0.25 (gr. iv), in water, c.c. 30.0 (℥i). This treatment is to be continued for from six weeks to two months.—GERALD DALTON in British Medical Journal.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

Subscription Price, including postage in U. S. and Canada

PER ANNUM IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	8.00

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, JANUARY 25, 1902.

A WIDER VIEW OF MULTIPLE NEURITIS.

MULTIPLE NEURITIS was once considered a comparatively rare affection, but at the present time its widespread occurrence is attracting considerable attention and more careful study is being devoted to its manifold etiology

The careful presentation of the causation of this affection in this week's issue of the MEDICAL NEWS, coming from so well-known an authority as Dr. M. Allen Starr, serves to bring into prominence certain etiological factors which have been obscure and others which have been neglected. The discussion also opens up an important field of medicolegal interest bearing on the relation of certain noxious trades and diseases of the nervous system.

The recent outbreak of arsenical neuritis in England, already referred to editorially in the MEDICAL NEWS, has served to focus the attention of neuropathologists on the rôle played by the metallic poisons in the production of peripheral nerve lesions. In Dr. Starr's paper it will be seen that the growth of many new industries in the United States in which arsenic, copper and lead are widely employed, is attended with a proportionate increase of danger to the working community, and physicians and legislators will do well to carefully scrutinize the factory inspection reports of European countries in order to avoid many of the pitfalls therein laid bare. Many of these industries are only in their infancy in this country, and a careful study of the cases of neuritis coming to us for diagnosis and treatment is imperative.

Alcohol as a causative factor in multiple neuritis has been recognized for many years, but it is of service to reflect that many "patent medicines," "tonics," "restorers," "blood purifiers," etc., are disguised alcoholic mixtures.

With the enormous output of rubber goods, bicycle, and automobile tires and innumerable electrical devices, the importance of poisoning by carbon disulphide is to be considered, and much more so the effects of the numerous synthetic coal-tar products, since every houshold now has its own box of headache, neuralgia and painful menstruation tablets, purchased from the druggist on his, not the physician's, responsibility.

It is particularly interesting to note that, from the neurologist's standpoint, confirmatory evidence of the value of antitoxin in diphtheria is found in a marked diminution of the cases of neuritis due to this disease. Attention is also called to the fact that our foreign possessions are going to bring a wider acquaintance with forms of multiple neuritis due to beriberi and the severer types of malaria.

Dr. Starr has thrown some light on a large group of cases heretofore regarded as idiopathic. These are really due, he says, to infections, many of them probably influenza-like, others perhaps gastro-enteric, still others due to the toxins elaborated in the rheumatic or gouty dyscrasiæ,

That Nature yields her secrets only after the most continued study is made apparent by this important résumé, and there still remain some cases which must, for the time, be regarded as idiopathic.

THE STATE CHARITIES BILL AGAIN.

THE intense excitement caused by Governor Odell's State Charities Bill shows that the people of the State, as well as those more intimately concerned with the management of the State Hospitals, realize that its success would be a degradation to the honor of our commonwealth.

The system by which the New York State Hospitals for the Insane have been looked after and improved by the voluntary service of the distinguished men of the community has been pointed out as an example to other States and other nations. The slow up-building of the system, its utter independence of political schemes,

the paternal philanthropic way in which the able men on the Boards of Managers have for terms of seven years visited, inspected, and personally cared for these homes of the afflicted, and all without thought of payment, approaches very nearly the ideal. The burden to the State has been voluntarily lightened by this system. It cannot be reduced by appointing a corps of one-year-service, powerless-to-act visitors whose services at $10.00 a day are limited to ten visits in their year of office. Hitherto, though the appropriation has been large, the people have had the satisfaction of knowing that every cent has been used for the care of the insane and not a penny has gone to support a political machine.

Why does Governor Odell wish to abolish the managers? Why does he want to pull down this honest system of which the State is so proud? Why does he want to drag the beneficent charities of the State into the machine? For economy's sake? Fudge! He knows there is no economy in his bill; but there is Power, Political Power! The Local Boards care personally for the petty needs of the insane, providing them with pleasures, comforts, entertainment, conferring with their relatives, and seeing that the helpless and unfortunates get the food and shelter and care that the State generously gives; but these worthy managers, it is true, are not of as much use to the machine as a centralized, closely-organized corps of indifferent paid visitors. And yet we do not impute to our present excellent Governor the desire to organize the machine more closely, for personal power. But we do most emphatically point out to him the danger to which he exposes the State Charities Commission from the influence of an unscrupulous governor.

Also we urge the fact that the bill will not save money; it will not provide efficient service; it will not ensure honest and wise care of the insane.

Moreover, we frankly caution our friends in the legislature that the little amendments and alterations and patches which the Governor may consent to stick on the bill to satisfy this or that objection have nothing to do with the case. The one point is that the Local Boards of Managers *must not be abolished.*

The very fact that the Lunacy Commission is composed of the most distinguished and honorable men is in itself a menace, if their honor is to be used as an argument to cloak the real issue; for it is only to such honorable men that the public would dream of confiding this power. They will not continue to serve, after the system has degenerated into that state of scandalous mismanagement from which Bellevue has just emerged.

After New York City has had the experience she has suffered under the centralized system of control of commissioners, and after she has finally adopted the trustee system, why should New York State go back and pick up the worn and worthless garment she has shed and wear it under pretense of economy?

OSTEOMYELITIS AND ITS DANGERS.

No better proof of the value of the doctrine of the infectious origin of most acute disease could well be adduced than the present position of our knowledge as to the etiology of osteomyelitis. A mystery to the acute observers of the preceding generation has become one of the triumphs of knowledge in ours. Now there is no difficulty in recognizing osteomyelitis as by no mere analogy, but in reality a furuncle of bone. The micro-organisms that in the hair follicles of the skin give rise to boils are exactly the same as those that within the shaft of a bone cause a purulent focus. Just as with regard to the cutaneous furuncle, the severity of the symptoms are dependent on the virulence of the causative micro-organisms and the resistive vitality of the patients at the moment. So, too, with regard to osteomyelitis. In but one point, but that most important, do the two pathological processes differ; the furuncle, owing to its proximity to the surface, has a marked tendency to spontaneous cure by evacuation, but the osteomyelitic process is unable to find or make an exit, and therefore demands prompt surgical intervention.

The recent discussion on osteomyelitis before the Medical Society of New York County brought out very well the present state of our knowledge with regard to this ailment. It will be found in abstract in our report of the very interesting orthopedic evening of the society in last week's issue of the Medical News.

The two forms in which osteomyelitis occurs are of great importance to the general practitioner. Spread of the suppurative process within the bone may in acute cases soon lead to death and sequestration of the larger part of a long bone, or to still more serious results if general sepsis, or even to sudden death if septic emboli result. Very early recognition, then, is of the greatest importance. In this perhaps more than in any other affection the Röntgen rays are of great assistance for diagnosis. Very early in a

case the outlines of the pus cavity with its lighter interior can be seen. In fact this constitutes the only sure method of early diagnosis. In chronic cases the existence of a limited purulent area in the shaft of a bone gives rise to referred pains in a neighboring joint. These conditions often persist for years with exacerbations of symptoms at irregular intervals and are often diagnosed as recurrent rheumatism.

The seriousness that osteomyelitis may assume is all the more surprising when the slightness of the cause that may occasion it is borne in mind. Any small cutaneous suppurative process, a furuncle, a felon, a slight ulcer, may prove the source of the purulent infection of the bone marrow. This has been demonstrated over and over again by careful bacteriological investigations, for the corresponding pus micro-organisms in pure cultures have been found in the external pus focus as well as in the internal bone lesion. Sometimes the original suppurative process is so slight that it has failed to be noticed by the patient himself and requires very careful thorough inspection for its detection. Not infrequently the causative micro-organisms gain an entrance through some lesion of the mucous membranes.

The frequency of typhoid osteomyelitis is now generally acknowledged. At times the typhoid bacilli seem to have lain dormant in bone marrow for many years (from five to ten) until the immunity of the system to typhoid virus has more or less worn off and then some slight injury to the bone arouses them to serious pathological activity. The original port of entry for the typhoid bacilli was evidently the specific ulcers of the intestinal mucous membranes.

Mouth and throat ulcers are also not infrequent sources of osteomyelitis. Special attention has been called to the fact that many cases of osteomyelitis originate in mouth infection due to unclean dental instruments. Many dentists fail to appreciate the necessity for the most careful cleanliness with regard to instruments used in the mouths of successive patients. Obscure infectious processes that originate in this way often failed to be traced to their true cause. Some of the mild pyemias that masquerade as anomalous rheumatism, neuritis or myositis, are due to dental carelessness. Too much stress cannot be laid on the necessity for dental asepsis or at least faithful antisepsis.

Recent advances in our knowlege of osteomyelitis are of the most practical character and involve especially the prophylaxis of the disease, its early recognition so as to prevent local extension or generalization, and its prompt effective treatment. The occurrence of osteomyelitic processes in the spinal column is now generally acknowledged. This clears up the mystery of many anomalous cases of so-called Pott's disease that healed rapidly and without deformity. The recognition of chronic cases explains many mysteries of diagnosis. In a word, a chapter of surgery with many points of interest for the general practitioner has received a development that holds out an encouraging prospect for other cognate types of disease that are as yet in obscurity.

CHILDREN AND MATCHES.

A STATUTE is apparently needed in this and the other States of the country to assist in decreasing the many cases of manslaughter which arise from the locking-in of young children by their mothers when leaving the house for longer or shorter periods. The case is a peculiar one, but one certainly within the proper jurisdiction of an adequate government and that without any danger of incurring, what to the individualistic Anglo-Saxon is a reproach, the charge of paternalism. One sometimes hears, indeed, of late that the people of the land are "too free," and perhaps this is a case in point.

The mental condition at the bottom of this calamitous and constantly recurring error of allowing one's children to be burned to death, with small chance of succor, seems to be thoughtlessness or, probably less often, ignorance—thoughtlessness and ignorance of the psychologic nature of the child. These are two conditions which it is alike the duty and the privilege of the State through its laws and boards of health to improve, if it would abolish one of the minor horrors of our civilization.

Nothing surely is to young children more interesting and attractive than fire, with its bright and lively flames, while matches inevitably entice by their crackling and brilliancy and are to the child the only available fireworks between Fourths of July. But, even in the family ruled in part by thoughtlessness and ignorance, young children are not commonly given matches to play with nor allowed unwatched to manipulate hot stoves, much less to build fires in the wood-box. These things are so absurd in the well-conducted household that they sound almost humorous to the competent parent, but assuredly such things are of all-too-frequent occurrence when direst and cruelest, because unmerited, tragedy results.

These things, matches and fires, considering their inherent interest for children, are precisely therefore those which children, completely freed from espionage for however short a time, would naturally seek, and, especially in the frequent cases in which due instruction as to the danger has not been inculcated, they would then run riot freely with these everywhere present agencies of an awful death. Moreover, few of the laity realize how little in the way of even superficial burns, especially when accompanied by great emotional shock, suffices to cause the death of a child.

So much for the causes of this common and hapless accident. The effects are only too obvious to every one who reads the news day by day in the papers. While exact statistics are not at hand, it must be obvious that in the course of a single year scores of children in this land are burned to death or wretchedly maimed for life by this one sort of criminal neglect on the part of the mothers and nurses. A statute making adequate punishment possible in the event of accident from this cause would seem to be required, and probably the mere placing of it on the books would call attention as nothing else could to this monstrous but wretchedly frequent effect of maternal thoughtlessness.

ECHOES AND NEWS.

NEW YORK.

Allied Hospitals Board.—Mayor Low has announced the appointment of the Board of Trustees of the Bellevue and Allied Hospitals, which board was created by the amended charter. Under the law the jurisdiction over Bellevue, Harlem, Gouverneur, Fordham and the Emergency Hospitals is taken away from the Department of Public Charities and lodged in the new board. The following were named and took the oath of office: Howard Townsend, for a term of one year; Theodore E. Tack, for the term of two years; Marcus Stine, for the term of three years; James K. Paulding, for the term of four years; Samuel Sachs, for the term of five years; Myles Tierney, for the term of six years; Dr. John W. Brannan, for the term of seven years. Dr. John W. Brannan was elected president of the Board and James K. Paulding secretary.

Economy with Cleanliness. — Commissioner Woodbury of the Street Cleaning Department has announced that he has contracted with the Long Island Railroad for the disposition of the street sweepings without loss to the city. The city undertakes to deliver 2,000 sacks of street refuse every day at certain docks on the East River to the railroad company. It is the purpose of the company to use the sweepings for fertilizing purposes. Under the Tammany administration the sweepings were carried to sea and dumped at a cost of $95 the scowload of 300 cubic yards. The Commissioner hopes eventually to dispose of the entire bulk, amounting to some 26,000 sacks, upon terms like those already made with the Long Island Railroad Company. The value of the street sweepings for fertilizing purposes was not recognized formerly, but Dr. Woodbury believes that the step he has taken to turn the street garbage into money will ultimately bring a revenue to the city.

Swift Abattoir Opposed.—Health Commissioner Ernest J. Lederle has listened for the second time to arguments for and against granting to Swift & Co. a permit to erect an abattoir on First Avenue, from Forty-fourth to Forty-fifth Street. At the first hearing Mr. Swift himself was present to urge that the abattoir which the meat concern proposes to erect would, because of the improvements which have been made in various directions, mechanical and scientific, be absolutely odorless, and therefore not objectionable to persons who live near the spot. But the Health Commissioner's office last week was filled with men and women who live in the locality in which it is proposed to erect the abattoir who submitted strong protests against its erection. The Rev. Dr. David H. Greer said that from 15,000 to 20,000 children lived within the radius which would be affected, and which was at present affected by the stench from the already existing abattoirs. "Their only refuge to get a little fresh air is the street," he said. "It is manifestly unfair to pollute for them the best air they can get—the air of the street." There were many others who said that they lived in the locality in which the abattoirs were located because they could neither sell nor rent their property.

City's Vaccine and Antitoxin All Right.—A committee of the Medical Association of the County of New York, which was appointed some time ago to investigate the conditions under which diphtheria antitoxin and vaccine virus were manufactured by the Board of Health of this city, made a report at a meeting in the Academy of Medicine January 20th. Dr. Wm. H. Park, who has charge of the department devoted to the production of diphtheria antitoxin, conducted the Committee through the laboratories and to the stables where the horses and calves are kept. They found that the horses selected for antitoxin production are under nine years of age and perfectly healthy, and are kept in a special building on East Fifty-seventh Street. About two-thirds of the horses had been kept in the basement, and about one-third on the first floor. "In order to prevent criticism, however, all the horses are now kept upstairs." All horses are exercised one hour daily except on very stormy days. The diphtheria toxin used in the injection of horses is produced by a culture obtained by the Department of Health laboratory seven years ago. Before treatment the horses are systematically injected with tetanus antitoxin, so as to prevent the possibility of their contracting tetanus, and since adopting this plan five years ago no horse has developed tetanus. As to vaccine virus, the calves used, the precautions for cleanliness employed, the care given to the stable, and the handling of the virus, have been investigated in detail. In a letter to the Committee Dr. Park says that the change in removing all the horses to the first floor where they will be kept "from now on" was made at their suggestion. The Committee, which comprised Drs. Brill, J. F. Erdmann, F. P. Hammond, and J. J. Nutt, concluded its report by saying that it is "unanimously agreed that the character, professional qualifications, and standing of the men engaged in the supervision and control of the manufacture of these products of the laboratory of the Health Department, none other than skilled help carrying out the details, are more than sufficient guarantee as to the quality of the curative sera and vaccine virus. These men represent the highest professional and scientific skill to be found in

this city in these departments, as is well known to the entire profession. The methods which are used, and which you have had presented, are beyond criticism. In conclusion it is most worthy of remark that the Committee has been unable to find any recorded cases of tetanus in New York following the use of antitoxin or vaccine virus, and that it is their opinion that these products of the laboratory of the Department of Health are absolutely safe."

Against the Osteopathy Bill.—A delegation from the New York State Medical Association will appear before the Judiciary Committee of the State Legislature on Wednesday, January 29th, to oppose the Brackett Osteopathic Bill, which proposes to except those of this society now practising from the examination required for a medical license. This subject was discussed by the Medical Association Monday evening and Dr. E. Eliot Harris briefly explained the purpose of the bill and said that it would be opposed on the ground that the Osteopaths' handling of contagious diseases is a positive danger to the community at large; that Osteopathy, so-called, is an agent used in the treatment of disease and as such has no more right or reason to be separated from the general practice of medicine than electricity, mechanical exercise, bathing, nursing, massage, or any other valuable agent or method used in the treatment of disease, and is not entitled to a special examining board.

Asylum Bill Condemned.—In response to an emergency call, a meeting of those interested in charitable works was held last week in the assembly room of the United Charities building, to discuss the bill now before the Legislature providing for the abolition of the boards of managers of the State hospitals for the insane. A resolution condemning the proposed legislation as "unwise, inexpedient, and contrary to good public policy" was unanimously adopted. The sense of the meeting was that the proposed plan of vesting the authority hitherto held by the managers in the State Commission of Lunacy and its visiting committees would promote extravagance rather than economy, would eliminate the gratuitous services of competent and sympathetic men and women, and would lead to a dangerous centralization of power, and might expose the hospitals to the unfortunate influences of partisan politics. Ex-Mayor Abram S. Hewitt and Prof. George F. Canfield of the Columbia Law School addressed the meeting. Mr. Hewitt said in part: "The city of New York has rescued itself from the grip of the serpent, and the Governor of the State is attempting to wipe out the work of a century. The Governor, no doubt, means well, but his mind has been crystallized on the subject of cost. His error is to me incomprehensible. I hope the Legislature will pause before it relegates our insane asylums to the barbarism of 200 years ago." Letters from the Rev. A. P. Doyle, of the Paulist Fathers and Morris K. Jesup, approving the fight against the bill, were read.

Neurological Society Condemns the Asylum Bill—At a meeting of the Council of the New York Neurological Society, held Monday last, the Asylum Bill was condemned and resolutions offered to urge its defeat. The clause advocating the abolition of the local managers was deemed especially undesirable.

Cost of State Charities.—What will Governor Odell say to the recommendations of the State Board of Charities submitted to the Legislature concerning the appropriations needed for the coming year? It will be remembered that in his annual message Governor Odell suggested that several hundred thousand dollars could be saved in the administration and management of the fourteen State charitable institutions each year. The Board recommends for the coming year appropriations for maintenance amounting to $1,197,000, or $21,000 more than for 1901; and for extraordinary expenses recommends appropriations aggregating $574,100, or $24,751 less than for last year. The receipts of these institutions for the fiscal year ending September 30, 1901, including balance on hand at the beginning of the year ($91,506.71), amounted to $1,399,669. Their expenditures aggregated $1,333,361; $915,043 being for maintenance, $384,370 for improvements, while $33,946 was returned to the State Treasurer, pursuant to the provisions of law. The number of their beneficiaries was 7,756. There are ten schools and institutions under private management, but mainly supported by State appropriations, and subject to the State Board's visitation and inspection. The receipts of these institutions for the fiscal year ending September 30, 1901, were from cash on hand, $43,907; from public sources, $685,623; from private sources, $210,784; total receipts, $940,316. Their expenditures aggregated $883,483, and the total number of their beneficiaries was 3,306.

Plans for the State Consumptive Hospital.—A meeting of the Board of Trustees of the State hospital for the care of persons suffering from incipient tuberculosis was held at Albany Wednesday last, when plans for the hospital buildings, to be erected on the site at Baybrook, between Lake Placid and Saranac, in the Adirondack region were passed on and approved. The Board has been in existence two years, and thus far the only work accomplished is the selection of a site for the hospital. It is understood now that there will be no further delay and that the trustees expect that the hospital buildings will be erected and ready for occupancy by next fall.

New York State Medical Society.—The following provisional program is announced: Papers.—Goitre, Medical and Surgical Treatment, by Thomas P. Scully, Rome; Phosphaturia, by James Pedersen, New York; Human Asymmetry, by W. S. Ely, Rochester; Malignant Tumors of the Periphery, Their Pathology and Treatment, by Thomas H. Manley, New York; A Case of Sarcoma of the Tonsil, by Arthur G. Root, Albany; The Treatment of Pelvic Suppuration, by Charles P. Noble, Philadelphia, Pa.; Gonorrhea of the Prostate, by John Van der Poel, New York; The Use and Abuse of Atropine and Other Mydriatics in Determining the Refraction of the Eye, by Frank Van Fleet, New York; Fractures of the Nose, by John O. Roe, Rochester; The Constitutional State versus Catarrhal Deafness, by Sargent F. Snow, Syracuse; The Educational Management of the Neurasthenic, by Edward B. Angell, Rochester; Discoveries in Pathology, by Mary Dixon Jones, New York; A New Method of Bisecting the Uterus in Abdominal Hysterectomy, by C. H. Richardson, Albany; The Traumatisms of Pregnancy, by Denslow Lewis, Chicago, Ill.; The Clinical Relations of the Systolic Murmurs Heard at the Pulmonary Area, by Morris Manges, New York; An Epidemic of Typhoid Fever in the Backwoods of Maine, by E. G. Brush, Mt. Vernon; Some Uses of Liquid Air in Pathology, with Demonstrations, by Henry W. Cattell, Philadelphia, Pa.; On a Case of Strangulated Ovary and Tube, by A. T. Bristow, Brooklyn; Toxic Dosage in the Treatment of Some Nervous Diseases, by William C. Krauss, Buffalo; Brachial Neuralgias and Arm Pains, by Charles L. Dana, New York; The Pathology of the Tissue Changes Caused by the Roentgen Rays, by Carl Beck, New York; The Sideroscope, by Thomas R. Pooley, New York; Glioma of the Retina, by Edward L. Peck, New York; On the Position of the

Eyes When at Rest, by Lucien Howe, Buffalo; The Smallpox Problem, by Ernest Wende, Buffalo; The Civilized Indian: His Physical Characteristics and Some of His Diseases, by A. D. Lake, Gowanda; Indian Medicine, by Nelson W. Wilson, Buffalo; *Symposium on Paresis:* (1) Etiology of Paresis, by Arthur W. Hurd, Buffalo; (2) The Early Diagnosis of Paresis, by Francis X. Dercum, Philadelphia, Pa.; (3) Comparative Frequency of Paresis, by Charles W. Wagner, Binghamton; (4) Pathology of Paresis, by Henry J. Berkeley, Baltimore, Md.; (5) Treatment of Paresis; Its Limitations and Expectations, by Edward Cowles, Boston, Mass.; Ringworm; a Note on its Treatment, by George Thomas Jackson, New York; A Case of Epilepsy with Possible Medico-legal Complications, by Frederick Sefton, Auburn; Acute Lymphatic Pseudoleucemia, with Report of Case and Autopsy, by John L. Heffron, Syracuse; The Changes of the Leucocytes in Disease as an Aid to Diagnosis and Prognosis, by Thomas R. Brown, Baltimore, Md.; An Unusual Case of Abscess of the Liver, by Edgar A. Vander Veer, Albany; Gunshot Wounds of the Liver, with Report of a Case, by E. W. Mulligan, Rochester; Concerning the Surgical Treatment of Peritoneal Tuberculosis, by John W. Whitbeck, Rochester; Unusual Herniæ, with a Report of Complete Hernia of the Bladder, Complicating a Strangulated Hernia, Requiring Resection of the Bowels, by John B. Harvie, Troy; *President's Address:* The Value to a Physician of Modern Methods of Diagnosis, by Henry L. Elsner, Syracuse; A New Symptom in the Diagnosis of Dystocia, Due to a Short Cord, by Samuel M. Brickner, New York; Pneumonia in Young Children, by W. P. Northrup, New York; A Contribution to the Surgery of the Chest, with a Clinical Report of Illustrative Cases, by Willis G. MacDonald, Albany; Partial Rupture of the Cecum from Obstruction and Distension; Operation; Recovery, by William Edwin Butler, Brooklyn; Tendon Transplantation in the Treatment of Paralytic Deformities, by Arthur W. Elting, Albany; *Symposium on Diseases of the Pancreas:* (1) Physiology and Physiological Chemistry of the Pancreas, by Prof. R. H. Chittenden, New Haven, Conn.; (2) Pathology of Pancreatic Diseases, by George Blumer, Albany; (3) The Diagnosis of Diseases of the Pancreas, by W. S. Thayer, Baltimore, Md.; (4) The Surgery of the Pancreas, by Roswell Park, Buffalo; (5) Clinical Indications for Surgical Interference in Acute Pancreatitis, by Joseph C. Bloodgood, Baltimore, Md.; Pneumogalactocele of the Breast, by J. Milton Mabbott, New York; A Simple Method for Determining the Percentage of Milk in Home Modifications, by Rowland G. Freeman, New York; Colles' Fracture, by D. W. Houston, Troy; Obesity of Adolescence, by Heinrich Stern, New York; An Unique Case of Double Dacryo-adenitis, by D. H. Wiesner, New York; Puerperal Hemorrhage, by George Seymour, Utica; What Shall Be Done with the Professional Midwife? by M. J. Lewi, New York; The Influence of Certain Diseases of the Nose and Throat on the Middle Ear, by Wendell C. Phillips, New York; A Further Contribution to the Study of Summer Diarrhea among Out-patients, by Charles G. Kerley, New York; Papers by V. G. Gibney, New York, and Charles H. Jewett, Brooklyn, titles to be announced.

PHILADELPHIA.

Medical Club Elects Officers.—The Medical Club of Philadelphia at its tenth annual meeting, held January 16th, elected the following officers: President, Dr. E. L. Duer (reelected); Vice-Presidents, Drs. Thomas H. Fenton and A. McAllister; Secretary, Dr. Guy Hinsdale; Treasurer, Dr. F. Savary Pearce. The Club now has 365 members and a sinking fund of $5,000. It is intended to devote this money to the purchase or erection of a suitable club-house.

Result of State Examination.—At the December meeting of the State Examining Board, 105 candidates were examined by the Allopathic Board, 21 of whom failed to pass. Of the 9 examined by the Homeopathic Board, 4 failed to attain the required average.

Hospital in Need of Assistance.—St. Timothy's Hospital, Roxborough, has recently been improved to meet the needs of its rapidly-growing work and has incurred a debt of $11,000. Until this is paid further urgently-needed additions must be postponed. It is the only hospital in a district of about eight miles square.

Coroner's Work for the Year 1901.—The work devolving upon Coroner Dugan in 1901 was greater than that of any other one year in the history of the office. Inquests were held in 2,793 cases; in 817 other cases investigated, inquests were thought unnecessary. Among the most important inquests were those on a boiler explosion on a steamboat, causing 24 deaths; the Market Street fire, which cost 22 lives; the Locust Street gasoline explosion with 8 deaths, and the Point Breeze oil fire which resulted in the death of 3 firemen. Special juries were impaneled in the above cases and their findings have resulted in the enactment of laws to prevent the repetition of such catastrophes.

Improvements at the Samaritan Hospital.—Plans have been made for the enlargement of the Samaritan Hospital to afford facilities for instruction to the classes in medicine at Temple College, the night school of medicine referred to in a previous issue. Two wings are to be added to the hospital, one 40 by 52 feet and the other 40 by 80 feet. In time the present building will be torn down and a wing like the larger one mentioned erected. In all improvements aggregating nearly half a million dollars are planned. The College holds only evening sessions and issues diplomas to its students only after they have passed the State Board of Medical Examiners.

Pink-eye Epidemic.—About 3,000 cases of "pink-eye" are reported in this city. Its prevalence is thought to be due to the insanitary condition of the streets because of their torn-up state.

The Wiener Verein.—This society, composed of physicians who have studied in Vienna, held its second annual meeting January 11th. Dr. James Tyson was elected president for the ensuing year.

County Medical Society Favors Vaccination.—On January 15th, for the first time since the present outbreak of smallpox, the Philadelphia County Medical Society placed itself on record regarding the disease in the following emphatic manner:

"*Whereas,* Smallpox is continuing to spread among the people of the city; and

Whereas, Sensational newspaper articles minimizing the importance of vaccination have caused a number of people to refuse the vaccination offered by the city physicians; and

Whereas, Of the 977 cases of smallpox admitted to the Municipal Hospital during 1901 there was not a single patient who had been successfully vaccinated within a period of four years, those afflicted being almost exclusively unvaccinated persons or adults unvaccinated since infancy; therefore be it

Resolved by the Philadelphia County Medical Society, representing the physicians of the city and county, That this Society deems it necessary to impress upon the community that universal vaccination is the most effective means of stamping out smallpox,

and that, although fumigation and disinfection are valuable adjuncts, they can by no possibility do away with the necessity for vaccination, since smallpox patients are the most important carriers of infection, and such infection cannot be influenced by the disinfection of smallpox. Be it further

Resolved, That publications which slur the importance of vaccination despite the incontrovertible testimony of 100 years are to be deprecated as contrary to the best interests of the community. Such articles are known to have dissuaded people from vaccination who have subsequently died of smallpox."

CHICAGO.

Officers of the Medical Examiners' Association.—At a meeting of this Association, held January 15th, the following officers were elected: President, Dr. Alfred C. Cotton; Vice-President, Dr. William E. Casselberry; Secretary, Dr. David J. Doherty, and Treasurer, Dr. C. P. Stringfield.

Chicago Neurological Society.—At the annual meeting of this Society, which was held January 16th, Dr. Daniel R. Brower was elected President; Dr. H. H. Donaldson, Vice-President; Dr. Charles Howard Lodor, Recording Secretary; Dr. Sydney Kuh, Treasurer, and Dr. Hugh T. Patrick, the retiring President, a member of the Council.

The Chicago Lying-in Hospital Dispensary.—This institution reports 2,000 consecutive confinement cases without a maternal death. In 3,763 consecutive labor cases, under the exclusive care of the dispensary, two mothers died, both from spontaneous rupture of the uterus. There were only eight septic fever cases. In two the uterus was cleaned out; in none was any other local treatment instituted. The number of directors has been decreased from 11 to 9.

Examinations of State Board of Health.—An unusually large number of candidates for medical certificates of practice took the examinations of the State Board of Health at its quarterly meeting at the Great Northern Hotel, January 16 and 17, 1902. Dr. James A. Egan, Secretary of the Board, presided. There were 49 candidates for physicians' certificates and 24 osteopaths. Four candidates for mid-wife certificates were also present. Dr. George W. Webster, of Chicago, is the President of the Board.

Officers of the Chicago Ophthalmological and Otological Society.—At the annual meeting of this Society, held January 14th, the following officers were elected: President, Dr. Wm. H. Wilder; Vice-President, Dr. C. P. Pinckard; Secretary-Treasurer, Dr. Brown Pusey; Committee on Membership, Dr. Casey A. Wood, Chairman, Dr. C. D. Wescott, and Dr. Lyman Ware. Dr. George F. Suker was elected to membership.

To Entertain Professor Haab of Zurich.—A committee, consisting of Drs. Frank Allport, F. C. Hotz, and Casey A. Wood, was appointed to take charge of the entertainment of Professor Haab, who contemplates visiting America this summer and will doubtless read a paper before the Ophthalmological Section of the American Medical Association.

Membership in Ophthalmological Society.—In view of the fact that there is a large number of applications for membership in this Society, Dr. H. V. Wurdemann of Milwaukee offered the following amendment: "Hereafter applications for membership in the Chicago Ophthalmological and Otological Society must be accompanied by a written original thesis upon some eye, ear, nose or throat subject, which is to be submitted to the Membership Committee and approved, then read and defended by the author in open meeting; the election to be held at the next meeting of the Society." This amendment will come up for adoption or rejection at the next monthly meeting.

Report of Illinois Factory Commission.—According to the annual report of the State Factory Commission, the employment of child-labor in Illinois has increased 39 per cent. in the last year. In 1900, the inspectors found 14,256 children at work in the factories, and in 1901 the number had grown to 19,839. During that time the increase in manufacture was only 9 per cent., and of women employed 16 per cent.; the gain in the total employed was 12 per cent., or less than a third of the increase in child-labor. The total number of convictions on account of the disobedience of the Child-Labor Law was 725.

Uniform Laws for Physicians.—Uniform medical legislation and universal recognition of certificates of State Boards of Health in all States are the objects of the "Reciprocal Federation of State Medical and Examining Boards," which was organized at a meeting held at the Great Northern Hotel, January 17th. Representatives of the States Boards of Illinois, Indiana, Wisconsin, and Michigan were present at the meeting, and communications were received from the State Boards of Ohio and Iowa to the effect that those organizations were in accord and sympathy with the movement. The new organization has long been desired by the medical profession, and it is expected that it will soon become national in character and will be supported by the various Medical Boards in every State in the Union. Another meeting will be held in May in Chicago and every State will be invited to send representatives. The prime object of the Association is to effect a uniformity of rules governing the examination and admission of physicians to practice. Heretofore each State has made its own laws, without regard to the laws of other States, which frequently has resulted in many hardships to members of the profession. A physician desiring to practise in a State other than the one in which he was first examined and granted a certificate would be required to stand the second examination and pay another fee. If he desired during his lifetime to practise in ten States, he would be compelled to submit to ten examinations. Under the reciprocal plan the certificates issued after an examination in one State will be good in the other States belonging to the organization. The examination required by the Federation may be more rigid than those required in many of the States at the present time, but, when once passed and a certificate issued on them, it will admit the holder to practice in all the other States. It is said that the plan was first proposed by Dr. Emil Amberg of Detroit, Mich., and set forth in the MEDICAL NEWS, and has been a subject of discussion in medical societies and in various State Boards for years. It is only recently that active steps were taken to form such an organization.

Officers of the Reciprocal Federation of State Medical and Examining Boards.—President, Dr. J. R. Currens of Two Rivers, Wis.; Vice-President, Dr. James M. Dinnen, of Fort Wayne, Ind.; Treasurer, Dr. Wm. A. Spurgeon, of Muncie, Ind.; Secretary, Dr. B. D. Harrison, of Sault St. Marie, Mich.

Modern Dietetic Preparations.—Dr. Arnold C. Klebs, in a paper on this subject, read before the Chicago Society of Internal Medicine, directed attention to the great progress made in this line and especially in the manufacture of nutrient preparations. In this country the progress in the manufacture has not kept pace with the advances of physiological chemistry and most of the preparations are of foreign make. Many

of the preparations are furnished at a relatively high cost and astonishingly small food value, and frequently have only a *raison d'être* on account of their stimulating qualities produced by a higher percentage of extractive substances and salts or by the addition of alcohol. The dietetic value of a good preparation is determined chiefly by its actual food value, determined by the amount of assimilable albumin it contains. The price of such albumin should not be higher than that contained in ordinary foodstuffs. The advances already made have opened possibilities to reduce the price even below this. Possible objections against the prolonged administration of such preparations should be overcome (1) by their having a pleasant taste or none at all; (2) by their small bulk, so that they can be given without overloading the digestive tract; (3) by their not being irritative to the digestive organs, even after prolonged use; (4) by their ready utilization in the metabolism, which can only be determined by experiment; (5) by their low price. These desiderata were fulfilled by a number of preparations now on the market. The author reports several analyses of the better known preparations. As nutrient additions to the diet, the pure albumin preparations, tropon, plasmon, soson, etc., with from 75 to 90 per cent. of assimilable albumin, have proved of the greatest value. The albumoses (somatose) can not be administered in doses sufficient to maintain the nitrogen equilibrium, but in small doses have nutrient value and are powerful digestive stimulants. The peptones, on account of their bitter and unpleasant taste and their irritating properties to the digestive organs, can practically be abandoned. The value of the larger number of other predigested foods is also, to say the least, doubtful. Meat extracts and liquid beef preparations can be used as valuable appetizing additions to the diet. The various carbohydrate and fat preparations, as well as the different combinations, were enumerated.

Pneumococcic Arthritis.—Dr. James B. Herrick read an abstract of a paper on this subject. He referred to the rarity of this condition, which occurs most frequently as a complication of acute croupous pneumonia. Cave, who reported a case in January, 1901, was able to find only thirty-one cases recorded in the literature. To this number Dr. Herrick adds seven, three of them being cases that had come under his own observation. These cases tended to confirm what had been previously observed by Leroux and others, *i.e.*, that the condition is most frequently met with in the larger joints; that it rarely occurs except as a complication of pneumonia, and that it is most likely to appear late in the disease or during convalescence. The influence of trauma was shown by the records of two cases. The prognosis is in general bad, because the condition occurs in those who are already ill of a serious disease, and because there is in these cases a pneumococcic septicemia, frequently with other localization in structures more vital than the joint. Death in many of these instances is due, not to the involvement of the joint, but to a coexisting empyema, endocarditis, pericarditis, or meningitis. The treatment that must be employed is as a rule surgical, yet some cases, particularly those in which the fluid in the joint was not purulent, make good recoveries under simple aspiration. Two such cases were reported by Dr. Herrick; in one of them, in which there had been an involvement of the elbow joint, the fluid withdrawn by aspiration was distinctly purulent. A recovery had followed in both instances.

Heart Failure and the Acute Infectious Fevers.—The author of this paper, Dr. N. S. Davis, Sr., had seen several cases of severe pneumonia, typhoid fever and diphtheria, in which the patients had been for several days taking from ten to sixteen ounces of whisky or brandy every twenty-four hours, with three hypodermic injections of strychnine, and liberal doses of digitalis, all for the sole purpose of strengthening the heart, and without the slightest reference to the special pathological conditions in each case causing the heart to be weak. He is satisfied that nearly all the cases of serious cardiac weakness or heart failure met with in practice are caused either by deficient oxygenation and decarbonization of the blood, by impairment of the action of the cardiac and vasomotor nerves, or by direct degenerative changes in the muscular structure of the heart itself. The most rational and important indications for treatment in established cases of pneumonia, diphtheria, typhoid and other infectious fevers are to aid Nature's own processes by securing for patients abundance of fresh pure air, strict cleanliness, free sponge bathing, pure water to drink, and the use of such diaphoretic, diuretic, and alterative medicines as will prompt, at least, natural activity in all the excretory structures of the body. It is equally important to avoid the giving of all such antipyretics and so-called cardiac stimulants as are known to diminish hemoglobin and free oxygen in the blood and to lessen both tissue metabolism and excretion. By their anesthetic and analgesic effects, they allay pain, quiet restlessness, lessen the pyrexia temporarily, but they directly favor the retention of the toxic agents in the blood until an unexpected fatal collapse ensues which is attributed to heart-failure. Although he has practised medicine many years, he has never seen a case of fatal heart-failure while that organ was supplied with well oxygenated arterial blood, while the metabolic and excretory functions were fairly active. But he had known many cases of both acute and chronic disease in which death resulted directly from both respiratory and cardiac paralysis, preceded by deficient internal distribution of oxygen and lessened activity of both tissue metabolism and excretion, while they were under the persistent influence of anesthetic and narcotic drugs.

Posterior Urethral Reinfection from the Bladder.—Dr. Louis E. Schmidt read a paper on this subject before the Chicago Medical Society. It is not unusual to observe acute relapses in the course of chronic urethral diseases. Harrison was the first to direct attention to recurrences of urethral reinfection after the healing of the posterior urethral inflammation from areas of the bladder which still continued to be affected. Harrison does not cite specific cases, but mentions the subject in a general way. For this reason it has appeared desirable to state the facts in closely-observed cases. Wertheimer and Kolischer have described cases of this kind in the female. Neither dilatation, massage of the posterior urethra and adnexa, irritating instillations, the drinking of beer or champagne, nor the sexual act will cause a relapse in these cases under consideration. These mechanical and chemical irritants would probably in most cases cause a relapse if the process were in the posterior urethra. Urethroscopy shows normal conditions except possibly more or less chronic changes. But, if these patients subject themselves to pernicious irritants which partly affect the bladder, a recurrence of the posterior urethral inflammation appears in a short time and a typical posterior gonorrhea results. Thus, reinfection occurring from the bladder can be proved with a certainty. The course is usually as follows: After the acquisition of a "cold," after the partaking of irritating foods or even after chronic constipation, cardinal symptoms of cystitis make their appearance. The patients who

never have had or possibly only have had slight symptoms referable to the bladder are taken suddenly ill. Frequently a chill is the premonitory symptom and often a fever continues. Then, in the course of two or three days a urethral discharge, which is usually never copious, makes its appearance, varying somewhat in color and consistency with the presence of the gonococcus. With all this the typical signs and symptoms of a posterior urethritis become apparent. If under rational treatment the posterior urethral inflammation is allayed and the acute bladder symptoms are made to disappear, there is apparently no involvement of the bladder; yet, when the bladder is again subjected to the agents already mentioned, the same course of events may recur. A more careful examination of these cases reveals the following conditions: The trigonum is the seat of a chronic inflammation; the characteristics luster is lost; the vessels are apparently obliterated; the mucous membrane appears like dark red velvet, and within the area, here and there, are distributed brownish-red spots of varying size. The posterior border of the internal urethral orifice is swollen; the epithelial cells edematous, and these sway more or less like a net in the fluid which fills the bladder. The practical deductions from these observations are that every case of apparently-cured chronic posterior urethritis, if doubt exists, should be cystoscoped in order to recognize any latent bladder disease, and, if such be present, it should be treated accordingly. Old and circumscribed cases of trigonum cystitis always require energetic treatment. If it is not possible to attain the desired object with instillations, the entire granulating surface of the trigonum can be thoroughly curetted in order to obtain a permanent cure. This procedure is readily done under local anesthesia with a Kolischer cystoscope.

CANADA.

Gift to Science.—Mr. E. S. Bronson, a prominent citizen of Ottawa, Ont., has donated a large sum of money to the McGill Medical Faculty for researches in the possible methods for the cure of consumption. Dr. A. G. Nichol will conduct the work under the supervision of Professor Adami.

Lecture by Sir James Grant.—"How to Live to Prolong Life" was the subject of a lecture delivered one evening last week in Toronto by Sir James Grant, Ottawa, who has been physician to Canada's Governors-General since the time of Lord Monck. The lecture was in aid of the Women's Residence of Victoria University, and during its deliverance Sir James took occasion to advocate the medical inspection of schools and his opposition to a prohibitory liquor law for Ontario.

New Civic Hospital for Montreal.—At a recent meeting of the Hygienic Committee of Montreal, Dr. Laberge, the Medical Officer of Health, presented an important report upon the great necessity for a new Civic Hospital for that city. The present hospital has been used for the recent outbreak of smallpox, and the city is now without a regular hospital for patients suffering from diphtheria or other contagious diseases.

Amalgamation of Medical College and Hospital.—The Governors of the Western Hospital, Montreal, and the Governors of the Medical Faculty of Bishop's College University, respectively, have come to a definite understanding that it will be in the interests of both institutions if an amalgamation be effected. Owing to the increased prosperity of the Western Hospital, a new building has long been desired, and under the present arrnagements this will be carried out at once and the Medical Faculty of Bishop's will take possession of the old hospital building when the new hospital is completed. This is expected to be about the beginning of the autumn session of 1893.

Vaccination Items.—"The Saints," a local sect near St. Catherine's, Ont., are causing trouble for the health authorities in that district. An outbreak of smallpox has occurred among them, but they all refuse on any terms to be vaccinated. They have, therefore, been quarantined *en masse*. Dr. Bryce has been consulted in the matter and has advised that the employment of force will be quite justified, and it will be a case of get vaccinated or go to jail.—The number of people vaccinated in Montreal since last October up to the present time totals 19,000.

Personals.—Dr. Phillips Weatherbe of Wolfville, N. S., has been apointed as supernumerary to the Canadian Field Hospital for South Africa.—Drs. Leslie and Jennie Dow of Toronto return for the China Mission Field on January 27th.—Principal Petersen, Dean Roddick of the Medical Faculty and Dr. Ruttan will represent McGill University at the annual dinner of the New England Society of McGill graduates to be held at Boston on January 23d.—Dr. E. P. Lachapelle is a candidate for mayoralty honors at the coming municipal elections of Montreal.—Dr. A. G. Macdougal, house surgeon of the General Hospital, Toronto, has been appointed civil medical attaché to the regiment in charge of the Boer prisoners at Hamilton, Bermuda.—Dr. Telesphore Parizeau has returned from abroad and has been appointed professor of pathological anatomy at Laval University, Quebec.—Dr. O. Bjornson of Winnipeg and Dr. B. J. Bjornson of North Dakota left Winipeg January 9th for a year in European hospitals; both are graduates of the Manitoba Medical College and were formerly house surgeons at the Winnipeg General Hospital.—Dr. Gordon Bell, provincial bacteriologist of Manitoba, and Dr. Holmes Simpson, secretary of the Board of Health, left Winnipeg January 13th for St. Paul, where they will attend a convention of medical men for the purpose of discussing the smallpox outbreak in districts between St. Paul and Winnipeg.—Dr. Macdonald, superintendent of the hospital at Dawson City, is paying a visit to Montreal; he states that there has been comparatively little sickness in the Yukon this year.—Dr. W. H. Groves, a graduate of Toronto University, has been appointed surgeon of the R. M. S. "Sekondi," flagship of the African Steamship Company, plying between Liverpool and the West coast of Africa.—The Hon. Dr. W. H. Montague has returned to Canada after having spent a year in New Zealand, Australia, in the interests of the Independent Order of Foresters.—Dr. N. A. Powell, President of the Ontario Medical Association, entertained Dr. W. H. Drummond of Montreal, the author of "L'Habitant" and "Johnny Corteau" on the evening of January 17th while the latter was in Toronto to deliver the first Toronto University Saturday afternoon lecture of the present season. A large number of the medical fraternity spent a most enjoyable evening with both gentlemen.

Indian Vital Statistics.—The aggregate increase of the total Indian population for the whole of Canada is 517 over last year, the population in 1901 being 99,527. There were 2,479 births during 1901 and 2,240 deaths. In 1900 there were 2,333 births and 2,567 deaths. Female child-marriage is still to some extent practised among the Blackfeet, Piegans and Bloods, and in order to put it down entirely prohibition of the custom may eventually have to be resorted to.

GENERAL.

Centenarians in Germany.—Insurance tables show that in Germany only one person in 10,000 reaches the age of 100 years.

VI. French Medical Congress.—This Congress will be held at Toulouse during the Easter holidays. Prof. Lemoine will preside.

No Smallpox in Hackensack.—It has been stated that, notwithstanding the reports concerning an outbreak of smallpox which were noted in the Medical News of January 11th, there is not a case of smallpox in Hackensack, N. J., nor has there been any for the past two years.

To Found a Sanatorium in Colorado Springs.—Gen. William J. Palmer has donated 100 acres and $50,000 to found a sanatorium in Colorado Springs. As already planned, two buildings will cost $200,000 and $50,000 respectively. The first will accommodate 100 patients who are able to pay a fair price for treatment. The class who can pay little or nothing will be accommodated in the other building to the number of fifty. Revenue from the large building will mainly support the smaller one. The sanatorium will be conducted on the German theory. The sanatorium will be east of the city, to procure the purest air and freedom from dust and smoke. The medical staff and the board of trustees are yet to be selected. A company will be incorporated. A large part of the money has already been subscribed.

Labrador Medical Mission.—Along more than a thousand miles of seacoast in Newfoundland and Labrador there are no doctors except those of the Labrador Medical Mission. Yet medical service is greatly needed. The resident and summer population of these coasts reaches from twenty to forty thousand. Life is a hard struggle for them and disease is frequent. They are largely subject to accidents, poisoned wounds, eye-disease, digestive troubles, scurvy, consumption, and various epidemic diseases. Their only possible relief from these conditions and from the terrible suffering, crippling, death and destitution resulting from them comes from the work of the Mission. This Mission deals with over 2,000 cases every year. It maintains a finely-equipped hospital steamer and two hospitals on the Labrador shore and is building a third hospital in Northern Newfoundland.

Journal of Obstetrics and Gynecology of the British Empire.—This new journal, noted in our "London Letter" of some time past, is just to hand and editors and publishers alike deserve credit for its excellent appearance. It is a large octavo of 128 pages, handsomely printed and well bound. An analysis of its contents will shortly be given in the "Medical Progress" columns of the Medical News.

Dr. Rixey to Succeed Van Reypen.—The expected application of Rear Admiral William K. Van Reypen, Surgeon-General of the Navy, for retirement after forty years' active service, was made to the Secretary of the Navy January 15th. Admiral Van Reypen will be succeeded by Medical Inspector Presley M. Rixey, U.S.N., who was attending physician to the McKinley family and is now occupying a similar position with the Roosevelts.

Obligatory Hospital Service.—A year's service in a hospital has been made obligatory to the medical graduate in Budapest; four months are to be given to the medical wards, two to the surgical and two to the gynecological; the remaining four months are to be passed in any department selected by the interne.

Obituary.—The death of Hugo von Ziemssen, in Munich, January 21st, removed one of the greatest medical and scientific men of the age. He was born in Greifswald December 13, 1829, and during the epoch-making latter half of the nineteenth century was one of the leaders of scientific thought. With the praise that is given to such men as Pasteur, Koch, Virchow, and others who have opened the avenues of pure science and revolutionized theories, we sometimes forget that their discoveries must be made practical in the hospitals and clinics before they receive their valuation stamp and will pass as scientific currency. Ziemssen was a master clinician and a great physician. The scientific institute for clinical instruction which he established at Munich has served as a model for all lands. His practical experiments in applying the discoveries of the age to the practice of medicine have appeared in authoritative treatises on the cold-water treatment of typhoid fever, the treatment of pneumonia, tumors of the stomach, and on a vast number of other subjects, among which the use of electricity in medicine is important. He is best known to physicians the world over by his enormous seventeen-volume work, "Handbuch der speciellen Pathologie und Therapie," popularly known in America as "Ziemssen's Encyclopedia," which he wrote in collaboration with other eminent specialists. He was also for thirty-seven years the coeditor with Zenker of the *Deutsche Archiv für klinische Medicin*. Probably no one man did more in the last half century to deserve the name of "Great Physician" than Ziemssen through his writing and his medical work.

Dr. William Mervin Smith, who for twelve years was Health Officer of the Port of New York, died in Redlands, Cal., Friday, January 17th, in his seventy-sixth year. He had an active career in politics, being twice elected to the Legislature and several times a delegate to national conventions, notably to that at which Lincoln was nominated. He was also Surgeon-General on Governor Dix's staff, and in the Civil War was Surgeon of the Third Brigade. He lived in Brooklyn for many years after his retirement from office.

Dr. Torrance Sparham of Brockville, Ont., the oldest practitioner in that town, died suddenly January 11th at the age of eighty-nine years. Dr. Sparham was graduated from McGill University and had resided in Brockville for forty years. He was of an inventive turn of mind and had patented artificial limbs which are said to be still largely in use.

Dr. Charles L. Bonnell, a prominent physician and surgeon, died recently at his home, No. 3 Hanson Place, Brooklyn. He was born in Dublin in 1848 and was graduated from Wesleyan College in 1868. After two years at the College of Physicians and Surgeons, in New York City, he received the degree of M.D. from the Hahnemann Medical College in Philadelphia. He was resident surgeon and lecturer at the Brooklyn Homeopathic Hospital and was chief of staff for six years. He was also a member of the staff and lecturer at the Brooklyn Mechanical Hospital and consulting surgeon at the Memorial Hospital for Women and Children. He was a member of the New York State Homeopathic Medical Society and of the Kings County Homeopathic Medical Society.

Dr. J. T. Eskridge, neurologist and alienist, died of tuberculosis in Denver January 16th at the age of fifty-four years. Because of pulmonary tuberculosis, Dr. Eskridge went to Colorado in the early eighties and soon after arriving there devoted himself entirely to the specialty in which he became distinguished. He was a Fellow of the American Neurological Association and was neurologist to various hospitals in Denver.

Dr. Clayton Parkhill, well known as a surgeon and

a writer, died in Denver January 16th at the age of forty-one years. Dr. Parkhill was a fellow of the American Surgical Association, a member of the American Medical Association and of various State and local societies. He had practised surgery in Denver continuously for fifteen years and enjoyed a wide reputation and an excellent practise.

Resolutions Concerning Death of Dr. Parkhill.—The following resolutions were adopted by the Medical Board of St. Luke's Hospital, Denver, on the death of Dr. Clayton Parkhill: "The medical and surgical staff of St. Luke's hospital is called upon to mourn the death of one of its most prominent members.

"Dr. Clayton Parkhill was appointed attending surgeon to the hospital in 1887 and served continuously in that capacity until his death. As a surgeon he was painstaking, intelligent and careful, successful in his work, kind and gentle in the treatment of his patients. As a man, he was courteous and amiable; as a colleague he was companionable and helpful.

"Dr. Parkhill was one of the most brilliant of operators and the profession is indebted to him for many useful and practical surgical inventions. His counsel was eagerly sought by students and practitioners. As a writer he was clear and forcible; as a lecturer he was eloquent and thorough. He was in truth among the distinguished of American surgeons and did much to shed luster on his chosen profession. At the breaking out of the Spanish-American war he was among the first to respond to the call of duty and as a military surgeon he deservedly held high rank.

"The staff of this hospital desires to record its appreciation of his long and valuable services to the institution and of his many endearing personal qualities; and it extends to his bereaved family and friends its profound sympathy."

Dr. Kingston Goddard, coroner of Philadelphia from 1874 to 1877, died of Bright's disease on January 19th.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, January 11, 1902.

A CANCER CRUSADE—THE SINEWS OF WAR NEEDED—CANCER RESEARCH IN ENGLAND—THE PROFESSION OF SCOTLAND AND THE GENERAL MEDICAL COUNCIL—VIOLET LEAVES IN CANCER: SEQUEL OF THE CASE OF "CURE"—THE MEDICAL PROFESSION OF GREAT BRITAIN AND TEETOTALISM.

THE munificent donation for the purposes of the crusade against consumption mentioned in my last letter has aroused a hope that a benefactor may come forfard to help in the fight against cancer. One or two efforts have been made within the last few years to organize a league against that fell disease, the ravages of which seem to become more extensive every year, but initiated by obscure, though doubtless well-meaning men, they have flickered out almost at once. It is stated in some of the daily papers that "a scheme is ready to hand, framed under the joint auspices of the Royal Colleges of Physicians and Surgeons, for the conduct of the continuous investigation that is necessary; but for this purpose at least £100,000 is required." I have no doubt that $500,000 would be of considerable use in such a research, though it is quite possible that much more would be required, for Nature does not sell her secrets for gold. But it is not the fact that a scheme of any kind has been framed by the Colleges. The matter is, I believe, under consideration by the authorities of the two Colleges, but no definite agreement has been arrived at. Systematic researches on the pathology of cancer have for some time past been carried on in a laboratory attached to the Middlesex Hospital, which has had a special cancer ward since 1792. Two years ago a wing intended exclusively for female sufferers from cancer was opened. This wing has accommodation for forty cases, while a ward in the main building, with nine beds, is reserved for male patients. They are kept in the hospital till they are cured or till they find surcease of suffering in death. There is thus a large amount of material for the study of cancer in all its aspects, and much may be hoped from the work of Mr. A. G. R. Foulerton, the director of research, and his assistants. But they are hampered by want of sufficient funds. At the Cancer Hospital there has been in existence for many years a pathological department in which experimental research has been carried on. Here, too, the workers are crippled by want of adequate means, and an appeal has been made to the charitable public for help. The governing body of the hospital has now under consideration a scheme for greatly enlarging their laboratories with the view of making the work of investigation more extensive and more thorough. The public which takes its tone, as far as it can, from the King, will probably subscribe with fair liberality, for His Majesty delivered himself not long ago of an opinion that the investigation of cancer was a matter of urgent importance. The antivivisectionists, however, who would apparently prefer that the human race should be decimated by cancer than that a mouse should feel the prick of the inoculation-needle, are doing their best to divert subscriptions from hospitals which have research laboratories connected with them. They would doubtless have denounced the provision for research that is to be a feature of the King's sanatorium, but that they know they would damage their cause in the eyes of the British public by associating it with even the appearance of disloyalty. In this way our worship of royal idols sometimes works for good.

Reference has been made in previous letters to the profound indifference with which the medical profession in this country regards the question of medical reform. At the recent election of direct representatives on the General Medical Council more than half the profession in England did not vote. In Scotland, where, according to the testimony of Professor Clifford Allbutt and other English authorities, the intellectual standard of the average practitioner is higher than it is in England, considerably more than a third abstained from voting. The fact is that the frame of mind of the bulk of the profession in regard to reform is that of Gallio, who "cared for none of these things." A good illustration of their attitude toward our Medical Senate was afforded by a member of the profession, who, when urged to vote, asked, "What is the General Medical Council? Who are its members? Where does it meet? What does it do? What interest is it to me?" The hopeless apathy revealed by such questions is the greatest obstacle in the way of reform. But it is the reformers themselves who are in large measure responsible for the indifference which they are now at last beginning to recognize, for their foolish and impracticable proposals, their unstatesmanlike methods, and their violent language, have made most people look upon them as intolerable bores.

Some time ago I related for the edification of your readers the strange eventful history of an old lady who had got rid of a malignant tumor in the throat and neck, apparently as the result of the application of an infusion of violet leaves. I note that a contemporary which supplies sweetness and light to the medical profession of the City of Brotherly Love speaks of the story as a "fake." That it looks like a "fake" may be admitted; but, whatever explanation of the sequence of events may ultimately be forthcoming, it certainly is not a

"fake." The old lady is still quite well. There is a deep cavity in her throat where the tumor was, but no ulceration; on the outside of the neck there is nothing abnormal to be seen. Sections of the growth, which was pronounced by the Clinical Research Association and various histological experts to be of epitheliomatous character, have since been submitted to our highest authority on such matters. His judgment, given without any knowledge of the clinical history, was that, though not epitheliomatous, it was certainly malignant. After learning the facts of the case, however, his opinion seems to have become considerably less definite. Evidently, we have still a great deal to learn about cancer and malignant disease generally. It would further progress if the profession were to adopt a less Nihilistic attitude in regard to the disease, and especially if it were to keep what Gladstone called an "open mind" on the subject and not refuse to consider reports of cure simply because they are improbable. The issue of the case which has made such a sensation (deeply deplored, it is said, by the patient herself) is awaited with great interest.

Prominent members of the medical profession in this country have on several occasions made proclamations *urbi et orbi* on the subject of alcohol. The first which was drawn up by Mr. Julius Jeffreys, a Fellow of the Royal Society, in 1839, was signed by most of the leaders of the profession of that time, including Sir Benjamin Brodie, Sir James Clark, the trusted physician of Queen Victoria in the early days of her reign, Marshall Hall, Robert Lee, Partridge the anatomist, Richard Quain (not *Sir* Richard), President of the Royal College of Surgeons, Benjamin Travers and many others. The utterance is described as an outspoken declaration in favor of total abstinence. A second declaration to the same effect was made in 1847; it was signed by over 2,000 practitioners, among them being such men as Addison, Bright, Brodie, W. B. Carpenter, Copland (of the "Dictionary"), Henry Holland, Paris (author of *Pharmacologia*), Pereira, Prout, Forbes Winslow and others of light and leading, to use a phrase of Edmund Burke's appropriated by Lord Beaconsfield. A third manifesto issued some years later and signed by three hundred consulting physicians and surgeons was not so much a condemnation of alcohol as a protest against its therapeutic abuse, which was the result of the teaching of Anthony Todd Thomson and his disciples. The practice of total abstinence has now become considerably extended among members of the medical profession in Great Britain. It is estimated that there are in this country at least a thousand practitioners who not only preach abstinence, but practise what they preach. There is a British Medical Temperance Association which feels itself strong enough to make the propaganda of which it is the organ more aggressive in character. Acting in conjunction with the American Medical Temperance Association and the corresponding association in Germany it has decided to issue an international manifesto, declaring that "seeing that the common use of alcoholic beverages is always and everywhere followed, sooner or later, by moral, physical and social results of a most serious and threatening character, and that it is the cause, direct or indirect, of a very large proportion of the poverty, suffering, vice, crime, lunacy, disease and death, not only in the case of those who take such beverages, but in the case of others who are unavoidably associated with them, we feel warranted, nay, compelled to urge the general adoption of total abstinence from all intoxicating liquors as beverages, as the surest, simplest and quickest method of removing the evils which necessarily result from their use." The document is to be signed by doctors who are total abstainers.

TRANSACTIONS OF FOREIGN SOCIETIES.

British.

SMALLPOX AND VACCINATION.

J. MacCombie at the Hunterian Society, November 13, 1901, read a paper upon the differential diagnosis of smallpox which embodied also a communication upon the subject of vaccination. He says that he disregards the ethical aspect of vaccination and bases his observations solely upon smallpox hospital statistics and his own hospital experience. The hospital case-mortality in unvaccinated smallpox patients is from forty-five to fifty per cent., in vaccinated patients about eight per cent. The severity of an attack of smallpox in vaccinated subjects bears relationship to the efficacy of the vaccination. The basis of the smallpox statistics in London is the number and quality of the vaccination scars. Viewed in this light nearly twelve thousand cases of smallpox in vaccinated subjects show the following results: One good scar, 6.4 per cent.; two or three good scars, 3.7 per cent.; four or more good scars, 2.7 per cent.; one poor scar, 16.7 per cent.; two poor scars, 11.2 per cent.; three poor scars, 7.4 per cent.; four or more poor scars, 4.8 per cent. The case-mortality is therefore inversely proportioned to the number of deep scars; the range is as just stated. When he was treating the disease in the South Eastern Hospital he obtained statistics based on the actual area of vaccination surface and with regard to foveation. He measured the area of vaccination scars in 5,808 consecutive cases. At that time the Local Government Board standard for effective vaccination was not less than one-third of a square inch of foveated scar. He followed this standard and regarded as imperfectly vaccinated all those who showed an imperfectly foveated surface no matter how large the area. His results are as follows: Effective vaccination, 1,435; deaths 36, rate 2.5; ineffective, 4.373 cases; deaths, 373, rate 8.7. These figures appear to show the great advantage of extent of vaccinated surface and of degree of scaring in lessening the fatality of smallpox. While in charge of a large smallpox hospital, the protection afforded to officers, nurses and servants by vaccination and revaccination was remarkable. A very large number were employed, but only two contracted smallpox, one being a nurse and the other a ward-maid. The nurse was a determined anti-vaccinationist and during the pressure of work she somehow escaped vaccination and suffered a mild attack of unmodified smallpox. The servant had been revaccinated three times unsuccessfully and had a very mild attack of modified smallpox. It seems likely that if it were not for the protection afforded by vaccination and revaccination against smallpox, it would be impossible to obtain nurses and other employees in our smallpox hospitals. Smallpox does occur in a very few people who show good scars of successful revaccination. None of his staff who had been revaccinated ever contracted the disease, but he has had a patient who showed the scars of successful revaccination and still contracted the disease. This has been the fact, although they showed well foveated primary and secondary and repeated vaccination scars. It must be remembered, however, that in some individuals even an attack of smallpox itself does not protect against a second attack of the disease.

Major Greenwood followed with a paper on the present aspect of smallpox and vaccination, making especial allusion to Dr. Creighton's article in the "Encyclopædia Britannica." Three indictments may be made against this author: (1) The facts reported by no means necessarily support the deductions; (2) facts seemingly against vaccination are enlarged and facts favoring vaccination are briefly dismissed; (3) facts

standing on vastly different basis are treated as of equal value. Dr. Greenwood then showed the looseness of evidence upon which Creighton founded his conclusions, especially that certain diseases, including jaundice, are caused by vaccination. Syphilis, he appeared to believe, was originated *de novo* from vaccination. The decrease in smallpox he attributed to a change in the type of the disease. But this cause, if it existed, would scarcely explain the great diminution of it among children as compared with that among the general population. Decrease in the death-rate, Creighton says, has not occurred, as at the end of the eighteenth century it was also 18 per cent. Greenwood urged that statistics on mortality in the old epidemics are entirely untrustworthy. The Conscience Clause had caused the law to be treated with contempt and practically repealed the vaccination laws. Experience gained since passing the last Vaccination Act taught the following lessons: (1) The uselessness of throwing a sop to the antivaccinationist, war to the knife against vaccination in any form being his intention. (2) The administration of vaccination laws should not be intrusted to Boards of Guardians, but to Borough Councils, better to Health Departments, and best of all to some central authority not influenced by any local prejudices. (3) Freedom of the vaccination officer from control by any local authority, but subjection of him to the local Government Board or the central vaccination authority whose inspectors should report periodically how his instructions are being carried out. (4) Vaccination as now practised affords a protective inoculation against smallpox as powerful and trustworthy as that introduced by Lady Montague, without its dangers to the patient and without the risk of spreading the disease. (5) The efficient vaccination is shown by a scar not less than one-half inch square. Revaccination in adult life is always necessary, usually at intervals of not less than ten years. The so-called one spot vaccination is greatly to be condemned. (6) The efficiently-vaccinated patient rarely contracts smallpox, no matter how much he may be exposed. (7) Vaccination under suitable antiseptic precautions and with proper lymph has hardly any dangers of introducing other diseases. (8) No general sanitary measures can possibly take the place of vaccination as a protective against smallpox. (9) Compulsory vaccination especially among infants is highly desirable. It is the duty of the medical profession to lose no opportunity of impressing this fact upon the public and the law-makers.

W. A. BOND, Medical Officer of Health at Holburn, submitted a communication upon vaccination. The general experience among the nurses and the staff of the smallpox hospital was that they could expose themselves with almost complete impunity to smallpox provided they were efficiently revaccinated. In the Metropolis Asylums Board Hospitals no cases of smallpox had occurred during the past seven years, 1894 to 1900, inclusive. For ten years there have been no cases except in persons attacked before revaccination had been successful. During the thirty-five years preceding 1871 no case of smallpox was reported among the nurses and servants of the Highgate Smallpox Hospital. Since then the only case was that of a gardener who had not been revaccinated, making a total of sixty years with this case as the sole exception to absolutely complete immunity from smallpox. Other smallpox hospitals show similar results. Death from smallpox among the vaccinated is much less than among the unvaccinated. In London from 1891 to 1900, inclusive, the death-rate was 3.1 per cent. and in the unvaccinated 18.1 per cent. If all doubtful cases without evidence of vaccination and among whom the majority had probably never been vaccinated successfully were counted in the former series the death-rate would be only 4.8. In Leicester 198 vaccinated persons of all ages were attacked. Only one death occurred, that of the hospital laundress, age forty-five years, intemperate and not revaccinated since infancy. Of 154 unvaccinated patients 19 died, a rate of 12.3 per cent. Under the age of ten years the protection afforded by perfect vaccination is still very much greater. The statistics included patients who showed good, bad and indifferent vaccination scars and some in whom vaccination had never been done. The records also give evidence of the fact that the attack-rate was smaller among the vaccinated than among the unvaccinated and the type of the disease was much less severe among the vaccinated. Marson has given a record of 14,000 cases among whom those having four or more deep vaccination scars were much better protected than those who had less. Other observers have proved that large, deep scars always give better protection. Revaccination Dr. Bond discussed in concluding in the following light: In the London post-office from 1870 to 1880, inclusive, and embracing the epidemic of 1871, only ten slight cases occurred without a death. In Sheffield and Warrington in the post-office and police force there was not one attack among the revaccinated. Since 1874, when revaccination became compulsory throughout Germany, there have been very few deaths from smallpox. In the German Army not one death has occurred from smallpox.

A visitor said that he was much astonished that so many people in England should be glad to hear a discussion on smallpox and vaccination, because in Germany smallpox does not trouble the community at all. Practically speaking it had been wiped out. By taking the statistics as they occur from year to year, it would be found that as a rule in Prussia the cases of smallpox nearly always occur on the frontier. He stated that there was hardly ever a death from smallpox in the army of Germany to-day—at least in the Prussian army. Vaccination is compulsory before the age of two years, after twelve years of age, and for a soldier at the time he enters the army.

DUNDAS GRANT, the President of the Society, stated that in his early practice in London he had seen smallpox. One of his earliest experiences he told in the following anecdote: He was called to a house where two young men were lying in bed stricken with smallpox. There were a number of abscesses all over their bodies. Two others in this family had recovered and two had died. The doctor said, "This says very little for vaccination." The man replied, "I have been a very foolish man. The fact is that I have always considered my blood and my wife's blood so pure that we would not have it mixed with any contamination whatever. The result is that I have lost two of my family and the only member who has escaped is the little baby, who has been vaccinated." Similarly he quoted from experience tending to prove the great value of vaccination and frequent revaccination.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held January 2, 1902.

The Vice-President, Hermann Knapp, M.D., in the Chair.

THE scientific portion of the meeting consisted in the continuation of a symposium on tuberculosis from the last meeting.

Present Need of Sanatoria.—Dr. George L. Peabody lamented the slowness of the process of recogni-

tion of the necessity for sanatoria in this country. The people are only just waking up to the crying need of special institutions for the care of tuberculous patients. European countries are far in advance in this matter. There are now 33 sanatoria in Germany. Eleven of these were erected in 1900. Thirteen of them were completed in 1901. There are fourteen new sanatoria projected, most of which will be finished during the present year. In Germany there is sanatorium accommodation for over 3,200 tuberculous patients. At the end of 1901, however, it was generally felt that they were as yet unable to care for tuberculous patients as they would like to. At the present time the Germans are engaged especially in the development of a movement for the foundation of polyclinics in which tuberculosis may be recognized at very early stages and observation stations in which suspected incipient cases may be kept under watchful supervision. With this is connected a movement, eminently philanthropic in character, for the maintenance of the families of patients during the absence of the usual financial support. This represents a completeness of sympathetic view with regard to tuberculosis that shows a spirit well worthy of imitation. Seventy-five per cent. of the patients admitted to German sanatoria are restored to usefulness within three months. As the result of the habits of sanitary living which have been insisted on for these patients on their return home, they become centers for the diffusion of sanitary knowledge of the most precious kind. It is well known that such patients are of great influence in preventing the further spread of tuberculosis in the families of relatives and friends.

Situation at Sanatoria.—There is a decided difference of opinion as to the location most suitable for sanatoria. Some prefer an elevated station; others think a lower situation quite as therapeutically effective. Some authorities insist that tuberculous patients do better in cold weather, others in warm weather. There is also a difference of opinion as to the value of exercise in the treatment of tuberculosis. Some say that the lungs need to be set at rest during the course of a tuberculous process, just as a tuberculous joint must be set at rest. All agree that even a small amount of fever is a contraindication to exercise. This has its influence with regard to the selection of a hilly site for the erection of a sanatorium. All are now agreed that open air is the most necessary element in the therapeutics of tuberculosis. The conviction of the benefit to be derived from life in the open air has been in the minds of many physicians for a long time. Many years ago Trousseau in Paris called Dr. Peabody's attention to the relative infrequency of tuberculosis among cab-drivers, although they are exposed to all the inclemencies of the weather and are especially liable to contract habits with regard to alcoholism which are now known particularly to favor the development of tuberculosis. The life of the cab-driver, almost entirely in the open air and yet without much exercise, is the ideal life for a tuberculous patient. The German Red Cross Society have established an institution to which patients may go for the day and be under the care of trained nurses and physicians, returning home at night to sleep. There is no doubt that such a system can be of great therapeutic value. Patients are educated to realize the necessity for careful habits and are taught just what is necessary for their own good. Moreover, such institutions are of distinct educational value in preventing the spread of tuberculosis, because the inmates of these institutions are taught very necessary hygienic rules.

French Sanatorium Movement.—The French have not been behind the Germans in the matter of providing sanatoria for the tuberculous. A special movement in Paris is that for tuberculous children. These children are sent to a sanatorium outside of the city and later when they are convalescent are sent to a home-colony where they have the opportunity to do farm-work. Under these circumstances patients do not relapse and, if they show any tendency to be delicate, are advised to continue farm-work as an occupation and not to go back to the city. At present there is no provision made for girls in this system, but it is expected that there soon will be. The best results have been obtained in children from three to seven years of age. Statistics show an average of 50 per cent. of cures.

America's Needs.—While all other countries have considerable organization in this matter the United States is wofully lacking. Above all, the necessity for taking care of its tuberculous poor must be impressed upon New York City. At present they are only provided, as has been well said, with a place in which to die. It can be shown to be a matter of actual economy for the city to care for them earlier. To permit these patients to associate freely with healthy citizens is to allow the serious danger of others becoming infected to persist. Much can be done for the tuberculous poor if efforts are only directed in the right way. America has a monument in this matter of which it may well be proud. At Saranac Dr. Trudeau has furnished an example worthy of imitation and has provided a source of inspiration for philanthropic medical men that should not prove abortive.

Phthisiophobia.—Dr. S. A. Knopf discussed the new disease, "too great fear of consumption," which has begun to spread and may have serious results. The Treasury Department of the United States has recently been very seriously infected by it. The Surgeon-General of the Marine Hospital Service recently decided that tuberculosis is a dangerous contagious disease. This decision would act to exclude all tuberculous patients coming to this country, even though very slightly affected, and it would apply to those coming in the first and second cabin as well as to steerage passengers. This decision is founded on an entire misunderstanding of the nature of tuberculosis. It is well known that contact *per se* with tuberculous patients is not dangerous. There is no scientific basis for the classification of tuberculosis among the dangerous diseases. A consumptive cough is not necessarily infective if the sputum is cared for. In New York Dr. Hermann M. Biggs, whose position in the matter is approved by Koch, says that workmen suffering from tuberculosis are not necessarily a source of infection to coworkers if they take proper sanitary precautions. Professors Janeway and Prudden declare that tuberculosis is a communicable, but not a contagious disease. To accept this decision of the Surgeon-General of the Marine Hospital Service is to stamp patients suffering from tuberculosis with the undeserved stigma that they are a constant source of danger to others. This will work serious harm to poor people. Already healthy men are being thrown out of employment not only because they have a persistent cough themselves, but because it has become known that they have a relative suffering from tuberculosis. Dr. Knopf has seen a poor washerwoman lose her position because of a chronic bronchial cough. Others find it difficult to procure positions when the story becomes known that they have relatives who have tuberculosis. This will entail almost untold suffering and hardship if the present impression in the matter is allowed to go uncorrected. The logical conclusion from the decision of the Treasury Department would be that tuberculosis, as a dangerous contagious disease, must be reported and strictly quarantined. This would be the logical outcome of the intemperate outcry against tuberculosis. As a matter of fact, the contiguity of tuberculous patients is not dangerous and even suscep-

tible persons are safer in a well-conducted sanatorium than elsewhere.

Vienna Experience.—Not far from Vienna there is a sanatorium for wealthy consumptives. It was proposed to found a similar institution nearby for the poor. The authorities of the original institution feared, however, for the bad name of the locality if another sanatorium were founded. The sanatorium for the poor, then, was founded in another and distant part of the suburbs of Vienna. Soon it began to be bruited about that the neighborhood of the new sanatorium was especially favorable to consumptives and for that reason had been selected by the distinguished specialist in pulmonary diseases who had the selection of the site for the sanatorium for the poor. The older resort was deserted and even the wealthier patients came to find quarters in the new neighborhood.

Vicinity of German Sanatoria.—Carefully collected statistics show that in the villages near the largest German sanatoria for consumption the death-rate from pulmonary tuberculosis has actually been reduced since the establishment of these institutions. The villagers have learned the sanitary lessons that are insisted on for the patients and so there has been less possibility of infection from tuberculous sputum. This is especially true of the villages of Görbersdorf and Falkenstein, near which famous sanatoria are situated. The recent scare in California with regard to tuberculosis served only to excite ridicule among those who realized the true conditions.

Regulation of Tuberculosis.—The recent extraordinary Treasury Department decision might, if pushed to its logical conclusion, separate families from one another and there are many families that have a tuberculous member. Such a decision is eminently un-American and utterly unscientific. There is need in this country for a national commission, such as they have in France and in Germany, to regulate tuberculosis. At the present moment even Canada is ahead in the matter of organization for the protection of the inhabitants against the spread of the disease. There is abundance of wealth and philanthropy is not lacking in the United States. What is needed is the assurance from the profession that great good can be accomplished in this way and wealth will not be slow to help in the battle against tuberculosis.

Fright Versus Education.—Meantime discrimination must be made against frightening people with regard to imaginary dangers from tuberculosis, and they must be educated to a realization of just what those dangers are. Fright will not serve any useful purpose and will only serve to throw discredit upon those who insist on dangers that are non-existent.

Dr. Knopf then presented a resolution for the consideration of the Academy. It was to the effect that the recent action of the Surgeon-General of the Marine Hospital Service and the action of the Treasury Department in accordance with it, in excluding tuberculous patients, was not based on clinical experience or scientific observation and was calculated to do harm rather than good. This resolution was laid over to be voted on, as is customary, at the next meeting of the Academy.

Crying Need for Sanatoria.—Dr. H. L. Loomis said that there is a crying need here in New York City for a sanatorium for tuberculous patients. What is needed is not a ward in a general hospital, but a building exclusively for consumptives, such as exists in Brompton Hospital in London. At the present moment the consumptive wards of Bellevue Hospital are pitiable to behold. The patients themselves are very little, if at all benefited, and they constitute a source of danger ever urgent for other patients in the hospital. When a patient suffering from tuberculosis is brought to any of the hospitals in Manhattan he is transferred as a rule within twenty-four hours to Bellevue. Here, by forced feeding and whisky, his condition is improved sufficiently to enable him to be moved. Then he is transferred to the City Hospital on Ward's Island, where a continuation of the forced feeding and alcohol gradually improves his condition, until he is able to be up and around. As a rule, the patient then asks to be allowed to go out, or, if not, he is discharged to make room for others who are in as pitiable a condition as he was himself. After a month, or two months, or three months, he comes back again and goes through the same circuit. From the history of a recent patient it was seen that he had made twelve such circuits. On one of his hospital rounds, the patient died. The exposure consequent upon the transfer from hospital to hospital and the changed mode of life after having been in a hospital hastened his end. If an institution for the better care of these patients were at hand, a not inconsiderable portion could be permanently cured and many of them could be benefited for long intervals. It would actually be a matter of economy to have such an institution. It would, moreover, prevent the spread of tuberculosis to no small extent. There is at present a building empty on Ward's Island, formerly rented to the Manhattan State Hospital for the Insane, which might be used to relieve the congestion in hospital wards and save many patients.

Dangers of Hospital Wards.—Dr. Loomis said that the present conditions in Bellevue were such that the dangers of the contraction of tuberculosis by other patients were almost inevitable. One out of three of the patients admitted to Bellevue is tuberculous. A tuberculous patient at the hospital may be put between a patient suffering from pneumonia and a patient suffering from typhoid fever with complicating bronchitis. Needless to say the risk of these other patients contracting tuberculosis is very great.

Sanatorium Advantages.—One of the principal advantages of a sanatorium is the constant medical supervision of patients. If city patients could be persuaded to come every day to their doctor they would do quite as well and perhaps better than if they were sent to a distant sanatorium. It is extremely difficult, however, to have patients understand the necessity for this and very hard also to have them follow out the rules as to diet and daily life that are laid down. Education must include the insistence upon the necessity for these points if tuberculous patients are to be improved at home.

Necessity for Careful Diagnosis.—Dr. J. E. Stubbert said that one of the important advantages of the sanatorium treatment of tuberculosis consists in the fact that very careful diagnosis is made of all cases. At the Loomis Sanatorium, for instance, all patients are examined, first, for physical signs, secondly, by the Röntgen rays, and, thirdly, as to their secretions. These observations are made by independent examiners and then notes are compared as to the conditions found. In this way the patient's exact condition is determined and the treatment most suitable for his case instituted. After all, it is not tuberculosis that must be treated, but a special individual tuberculous patient. All patients may be divided into these two classes—careful patients who faithfully follow directions given and careless patients who follow directions more or less for a few days and then on the slightest sign of improvement neglect important therapeutic measures. Careful patients recover even from somewhat extensive tuberculosis. Careless patients fail of ultimate improvement, even if they come in very incipient stages. They are unlikely, however, to come at a very early stage. It is important for the physician to study his cases and to treat each one individually. No single form of treat-

ment is always the best. A selection from the many recommendations that are made gives the most promising result. It is only by careful treatment of a great many symptoms and the faithful meeting of many indications that success comes in the treatment of tuberculosis. Undoubtedly the Government has a duty toward the tuberculous of the community. A sanatorium for the tuberculous, however, must not be run mainly with an idea to economy. It must not be conducted on the principle that the most successful management is that which cuts down expenses *per capita* as low as possible. For success in the treatment of tuberculous patients the saving of money must not be the prime object. Dr. Trudeau confesses that in his sanatorium it costs at least a dollar a day for each patient. At the Loomis Sanatorium a certain number of poor patients are taken and it costs more than a dollar a day to support them. Pay patients at Liberty are supported at an actual expense of over $15 a week.

Poverty and Tuberculosis.—Dr. Leonard Weber said that undoubtedly the prevalence of tuberculosis among the poor is due to poor feeding, poor housing and lack of ventilation. For these evils the best remedy is sanatoria supported by the Government. Sanatoria for thousands are needed. In addition, a large dispensary in which tuberculosis may be recognized in its early stages is needed. City and State aid will not be sufficient to supply the amount of room necessary for all the patients that will present themselves.

The Tuberculous Poor.—Dr. Freudenthal said that all are agreed that sanatoria are necessary. They must, however, be of a kind that can benefit not only the well-to-do, but those who are comparatively poor. The climate is not everything in the location of the sanatorium, nor in the selection of a place best for the treatment of tuberculosis. Neither Liberty nor Saranac is an ideal situation. Excellent results are obtained in the treatment of tuberculosis in the Jewish Hospital in Berlin in one of the most thickly-populated parts of the city. Undoubtedly, then, with proper facilities, much can be done without going far from New York City. Dr. Freudenthal says that many young persons ill with tuberculosis have very little to spend in their treatment. Seven dollars per week presents the maximum at times. If farms were to be obtained not far from the city on which such patients could live great good might be accomplished. Plenty of farms can be obtained cheap. Expensive sanatoria are not necessary. Tent colonies may accomplish all that is needed. This has been tried, experimentally, near Denver with great success. Dr. Freudenthal saw the benefit of tent-living for patients suffering from typhoid fever during the war between Germany and France. The patients asked to be allowed to remain in their tents even in October and November.

Need of Exercise.—Dr. Freudenthal does not believe in the rest cure for tuberculous patients. They should not only be allowed to, but should be advised to take up a farm-life. The product of their labor would help in the support of the sanatoria. If the patients were slow to recover, or if they showed a tendency to recurrence of the disease, they might be permitted to continue their farm occupations indefinitely.

Chance for Life.—Dr. Alfred Meyer said that the State owes all of its citizens a fighting chance for their lives. For tuberculous patients this can be secured only in sanatoria. There are 8,000 new cases of tuberculosis in New York City every year. When it was originally proposed that the State should take care of the insane, many said that the insane asylums would bankrupt the State. Now, however, 23,000 insane are cared for at an expense of $4,000,000, and it is just beginning to be realized how important and necessary a philanthropic duty this is for the State.

Change of Climate.—Dr. Edward G. Janeway said that no one who has seen the benefits that accrue from change of climate in many cases of incipient tuberculosis can argue that tuberculous patients do as well under city treatment. There is something in the change itself that does them good. In early life Dr. Janeway had a personal experience in this matter. For several winters he had a persistent bronchitis with quite a little cough. A number of remedies were taken without effect. A change of dwelling to another part of the State caused his persistent bronchitis to disappear, though he never took another dose of medicine for it. Sanatoria should be put in the most accessible place with the best possible location. Country sanatoria for incipient cases and hospitals for advanced cases are needed.

Encourage, Not Terrify.—Dr. Jacobi said that for many patients it is absolutely impossible to leave the city. It is not an unusual thing to find, however, that such patients, after careful examination by a physician who pronounces them tuberculous, are told that their lives absolutely depend upon their getting out of the city. They are told they must go at once to Colorado. Often between themselves and their relatives they have not the money even for their railroad fare, much less for living expenses away from home for a long time. Such advice is brutally thoughtless. Physicians must realize their responsibility in this matter and must keep before their minds the rule of Christian charity—to take care of even the least of the poor.

Sanatoria at Home.—Dr. Knopf said that patients often are compelled to continue their residence in the part of the country where their improvement has come. Sanatoria should be erected, then, as near as possible to the city, so as to make it easy for patients to take up their lives again after treatment.

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Stated Meeting, Held October 2, 1901.

The President, Alexander Lambert, M.D., in the Chair.

Dr. N. E. Brill, the retiring president, in introducing Dr. Alexander Lambert, thanked the members of the Society for the kindly courtesy with which they had assisted him in presiding over the meetings of the Society during the past year, and asked that the same courtesy be extended to his successor, who needed no formal introduction.

Dr. Alexander Lambert, in taking the chair, said that it was a source of real pleasure and one which he keenly appreciated to have been honored by the election to the presidency of the Society. It has always been the one society in which he had taken a personal interest, because he felt sure that it was an active working body and would develop from year to year. As to his intentions for the coming year, he said that he would endeavor to have presented papers, the subjects of which will be of practical interest, and which will be of such a nature as to make it worth while for the members to be present.

Acute Ascending Infection of the Kidney; Nephrectomy.—Dr. Alexander B. Johnson presented this patient, a woman of twenty-eight years, the mother of several children. She had been confined sixteen days before he had first seen her. The only trouble after the labor was that it was necessary to catheterize her. About one week previous to his seeing her she had been suddenly attacked with pain in the region of the left kidney, and this had been associated with chills

and fever. Her temperature at the time she was first seen by Dr. Johnson was 105° F. and the pulse was rapid and feeble. The urine was clear, but the microscope showed blood and pus-cells. Palpation in the left hypochondrium elicited extreme tenderness over the region of the kidney. He had operated upon her the next day. Under ether the slightly enlarged lower pole of the left kidney could be felt. An incision had been made below the free border of the ribs, extending from the outer border of the rectus to the outer border of the erector spinæ. On inspection, the kidney had appeared firm and tumefied at the lower pole. The pedicle was firmly ligated and the organ removed with scarcely any loss of blood. Her temperature at the time of the operation had been 105.2° F. and her pulse 134. Within the next three days it had gradually fallen to 99° F. and the pulse to 100, and convalescence had been established. Previous to the operation there had been a marked leucocytosis, but this had rapidly disappeared. She had left her bed on the eighteenth day, primary union having taken place except where a strand of gauze had been placed for drainage. The affected kidney was somewhat enlarged, and the diseased area was chiefly in the lower portion. The cortex was the seat of numerous minute abscesses. In the fresh state, purulent streaks could be seen following the course of the tubules down into the calices. The remainder of the kidney was in a condition of acute nephritis. The speaker said that the incision used allowed of making a small opening in the peritoneum, and with two fingers inside of the abdomen palpating the other kidney with great readiness. Another advantage was that the pedicle could be tied under the guidance of the eye, the kidney then being extirpated like any other tumor. It might be thought that the infection of the kidney had been a part of the general infection, and, while such was possible, it should be remembered that there was a history of catheterism and of an acute irritation of the bladder following this, together with a sudden appearance thereafter of chills and fever and pain in the loin. The rapid subsidence of the symptoms on the removal of the kidney was also opposed to such a view. Some years ago, on looking over the records of the Roosevelt Hospital, he had found but one case in which the kidney had been cut down upon in such an early stage of infection. That case had been one of infection in connection with an acute gonorrhea. Both kidneys had been infected and the patient had died.

Renal Calculus.—Dr. Johnson presented a youth of nineteen, whom he had first seen on August 14th of the present year. For five years he had suffered from perfectly characteristic attacks of renal colic referred to the left kidney. There had been no hematuria, but the urine had been pretty constantly purulent and small calculi had been passed *per urethram* from time to time.

The diagnosis in this case had been established by means of a radiograph. There were several large calculi found in the kidney. In this connection a number of radiographs of renal and ureteral calculi were exhibited. He had operated upon the young man through an incision similar to the one used in the other case. The kidney had been found greatly enlarged and the cortex everywhere thin. The pelvis was dilated and contained pus and a very large number of stones. The kidney had, of course, been removed and the wound had healed satisfactorily.

Operation for Ventral Hernia.—Dr. Johnson also exhibited a young man who had been operated upon by some surgeon on October 28, 1899, for an acute suppurative appendicitis. Following the operation he had suffered from a ventral hernia of some size. The operation which Dr. Johnson had done on the hernia had consisted in removing the cicatricial tissue on either side of the wound and separating the aponeurosis of the external oblique and the tendinous continuation of the internal oblique and transversalis. Internally, the anterior sheath of the rectus was separated and the sheath split throughout the length of the hernia. The rectus was freed very largely from its sheath and dragged outward. It was then attached to the under surface of the aponeurosis of the external oblique by a series of chromic catgut mattress stitches. The aponeurosis of the external oblique was then sewed up in front. This was the second patient upon whom he had done this operation, and in both instances the result had been extremely good. Neither patient had worn a belt.

Perineal Prostatectomy.—Dr. Johnson then presented three men upon whom he had done the operation of perineal prostatectomy. The first patient was sixty-three years of age and had been first seen two years ago. At that time there had been a marked cystitis and he had been suffering greatly. His prostate had been removed by making a curved cut, convex forward, in the perineum and vertical cut above the pubes, and pushing the prostate down to facilitate enucleation. The only peculiar feature of the operation was that neither the bladder nor the peritoneum was opened. The treatment after such an operation was less troublesome and the operation itself seemed to be somewhat less dangerous than the ordinary one. Of course, the operation would not be applicable to every case. The convalescence had been rapid, though the patient had suffered for a time, as these persons always do, from leakage of urine. There had been no treatment for over a year and the man was perfectly satisfied with his condition. The urine was voided with normal frequency; there was still half an ounce of residual urine. Erections were not as good as formerly. The second patient was fifty-eight years of age and had been first seen by the speaker last February. For some weeks previously he had been unable to urinate, catheterism had been difficult and painful, and was followed by bleeding. A prostate of medium size had been removed by Dr. Johnson by the operation already described. At present his urine was quite clear and there was no residual urine. He urinates three times in the day, and once at night, and his general condition has improved. The third patient, a man of fifty-seven, had been admitted to hospital on July 14, 1901, complaining of the first attack of retention of urine. On admission, sixty or more ounces of urine had been removed by catheter. The prostate was soft and considerably enlarged. There was no stricture and little or no cystitis. It was thought that an operation for the removal of the prostate would give him a good prospect of relief. This operation had proved quite difficult. As soon as the tube had been removed he had begun to pass all of his urine through the perineum, and after a number of weeks there had been an annoying incontinence. By irrigation with nitrate of silver the quantity of residual urine had steadily diminished, and it was probable that within a few weeks a cure would be complete.

A Plexiform Neuroma of the Back.—Dr. Johnson exhibited a specimen taken from a girl of ten years, who had been brought to him during the summer with a "lump" on her back. It was supposed to be a lipoma and the house surgeon was given permission to remove it. The tumor had proved to be a very rare one, a plexiform neuroma. The literature had been collated and published by Bruns. The tumor in this case measured 4½ inches in diameter and was situated beneath the skin, but not in the muscles. It was located

over the lower ribs and appeared to be the product of the degeneration of some of the posterior branches of the spinal nerves. These tumors had been described by Bruns as closely allied to elephantiasis. When exposed, the tumor had looked like a bundle of gelatinous worms. The gelatinous quality was probably due to a myxomatous change in the degenerated tissue. The nerve fibers had disappeared. The tumor in this case, as was the rule, was entirely painless. He had seen another case of the kind operated upon by Dr. Abbe That one had been on the neck. In the cases published by Bruns there were 30 in which the neck and face were involved, half of them being on the side of the forehead or on the upper eyelid. In seven of the cases the tumor was on the breast or back, and in three it had been on the extremities.

Question of Saving the Kidney.—Dr. Robert T. Morris asked how Dr. Johnson determined whether or not it was wise to save the kidney. He often found it very difficult to decide this question. Sometimes he found the kidney very much distended, a large stone blocking the pelvis, and yet the parenchyma would appear fairly healthy, though thinner than normal. On making an incision through the parenchyma and removing the calculus, the kidney seemed to be able to perform its function very well. In two such cases, however, he had found it necessary to remove the organ subsequently, one after about one year and the other after two years. The parenchyma had not contracted sufficiently to give a normal pelvis and enough urine had been retained to allow of the formation of gravel. In going over the literature of the subject he had not found discussed this question of which kidneys should be allowed to remain and which removed. He had never made use of the transverse incision used by Dr. Johnson, but had been very much struck with the apparent ease of an operation conducted through such an incision. It was evident that it gave easy access to the kidney. He would like to know whether this resulted in a strong abdominal wound; also how he sutures the oblique muscles and the transversalis in order to secure such a result. These muscles had different traction lines and, therefore, theoretically one would expect a weak abdominal wall. From palpation in this case it seemed to him that the abdominal wall was quite strong.

Dr. Johnson replied that the problem presented by the last speaker regarding what kidneys should be removed in stone cases was certainly a vexing and difficult one. Where the secreting substance of the kidney had been largely destroyed and the secretion was infectious, there could be little doubt of the wisdom of removing the kidney. However, if the greater part of the kidney structure remained normal and there were no abscesses or other evidences of a distinctly infectious process, and the stone could be easily removed and the patient's powers of resistance were good, he would be in favor of allowing the kidney to remain. If, on the other hand, there was a fairly intense degree of inflammation and the patient was feeble and had a septic temperature, he would advise removal of the kidney. There were also cases in which during the necessary manipulations for the removal of a large irregular calculus so much laceration of the kidney took place as to cause troublesome bleeding; here he would be in favor of removing the kidney. He had seen, he thought, persons die from operations done for the removal of stone from the kidney, the kidney being left behind, where recovery would probably have taken place if the kidney had been extirpated. Out of a considerable number of cases of stone and various inflammatory conditions that he had collected and many of which he had personally seen, the mortality had been notably higher than where the kidney had been left behind. In a general way, the local and general conditions must be carefully considered at the time of the operation in the individual case in order to answer this question. He had collected forty or more cases operated upon through this incision at Roosevelt Hospital, and no case had a hernia. He was in the habit of using an interrupted suture of fine chromic catgut or sometimes of ordinary catgut of medium size. The sutures were applied fairly closely and to each layer of muscles as accurately as could be done. In his opinion, one of the reasons why these cases had a strong abdominal wound was that the entire wound, with the exception of the posterior inch, had healed by primary union. Where the cut was made so high up the tendency to hernia was nothing like so great as where it was made lower down.

Dr. Morris said, regarding the case of ventral hernia, that he had operated upon a good many cases of ventral hernia by careful dissection and accurate suturing, sometimes splitting the two sheaths of the rectus and drawing it out. He had carefully avoided having these patients wear any support except for the first few days after getting out of bed. If these artificial supports were discarded early it seemed to him that the natural supports developed much more rapidly than where the supports were worn for a considerable time. He had published a series of experiments on rabbits and dogs emphasizing this point.

Radiography for Renal Calculi.—Dr. A. B. Johnson said that he had given a good deal of attention during the past year to the study of X-ray photography in connection with cases of renal calculi. He was of the opinion that the time was close at hand when negative diagnoses of renal calculus could be made in persons who are not very stout, *i.e.*, men under 160 and women under 140 pounds in weight. When, however, the abdomen was very thick the X-ray tube must be placed farther away, a longer exposure was requisite; the added density of a small soft renal calculus was little as compared with the total density of such an abdomen and back. In a thin individual having a fairly dense stone one occasionally secured remarkably brilliant pictures of even small stones. Radiographs of an exceedingly small stone were exhibited as an example of these exceptionally good results. In the case reported this evening in which there had been a very large number of stones in the kidney, one large stone showed in the radiograph while the hundreds of others present did not show, except as a diffuse shadow. The apparatus used for this purpose must be capable of giving a considerable amperage of current combined with high voltage. Special tubes are also necessary—tubes which allow the use of a large amount of current, but with very little resistance in the tubes, or, in other words, what are called low-vacuum tubes. High-vacuum tubes would show large calculi. An oxalate calculus would usually give a very dense shadow, while a very small phosphatic stone would be photographed with difficulty. It was very important that the individual should have had no meal for a number of hours before the taking of the picture; it was also desirable that the large intestine should be empty.

With slender individuals and proper apparatus a person with the requisite skill should be able by taking several pictures to make the diagnosis in most cases of renal calculus. The different pictures taken should be carefully compared in order to say whether certain shadows appear uniformly in all of the photographs. The tube should be so placed with reference to the body that the X-rays are directed through the abdomen from below upwards, for, when passed in the reverse direction the liver greatly interferes.

"Recent Studies in Immunity."—Dr. Alexander Lambert delivered this address.

BOOK REVIEWS.

SURGICAL APPLIED ANATOMY. By Sir FREDERICK TREVES, K.C.V.O., C.B., F.R.C.S., Sergeant Surgeon to H. M. The King; Surgeon in Ordinary to H. R. H. the Duke of Cornwall and York; Consulting Surgeon to the London Hospital. New Edition. Revised by the Author with Assistance of ARTHUR KEITH, M.D., F.R.C.S. Lea Brothers & Co., New York & Philadelphia.

STUDENT and practitioner alike will gladly welcome the new edition of this admirable and familiar book. It is no exaggeration to say that its text is exquisitely lucid in all details, its brisk and flowing language reminding one of a French text-book. Perhaps there is no one passage in it which more succinctly illustrates this characteristic than the following, in which the author discusses the anatomical objections that oppose themselves to the common conception of concussion of the cord. "The cord is, indeed, somewhat in the position of a caterpillar suspended by a thread in a phial of water. It would probably be difficult to disturb the internal economy of such an insect (even if it had a structure as elaborate as the cord) by other than violence that would be comparatively excessive." The description of the abdominal surface, together with the interesting characteristics of the walls and the discussion of the almost magic manner in which they guard the tender viscera from harm, is truly classic.

Indeed, this brilliant author, when given an opportunity to establish homologies between intricate anatomical conditions and the ordinary every-day affairs and objects of common observation and common life, shines with brilliancy peculiar to himself.

But while this work is one of very special merit, it is not without unpardonable defects. The illustrations are almost grotesque. They furnish examples of the most careless English art. It may in fact be said that with few exceptions there is little to justify their introduction. It is further to be regretted that in some instances the technic of some important operations is not up to date. In the discussion of stone in the bladder, for example, the operation for lateral lithotomy occupies three times the space accorded to the median and suprapubic operation. Another example, which seems to belong rather to archaic than modern technic, is that castration is cordially recommended to cause atrophy of the prostate. American surgeons have long since given up this idea.

In discussing the pancreas, the writer sets forth the relationship of this organ most clearly; but we are confronted with the startling statement that it "presents little of surgical interest." It is difficult to understand how Sir Frederick can have overlooked the brilliant work of his countryman, Mr. Mayo-Robson, on acute hemorrhagic pancreatitis.

Nevertheless, despite the numerous unfortunate illustrations and the sporadic instances of archaic technic, every reader must enjoy the book, albeit he will at the same time indulge the hope that ere long a really up-to-date edition will make its appearance.

STUDIES OF THE INTERNAL ANATOMY OF THE FACE. By M. H. CRYER, M.D., D.D.S., Professor of Oral Surgery, Department of Dentistry of the University of Pennsylvania. The S. S. White Dental Mfg. Co.

THERE is very little but high praise to be spoken of this valuable addition to our knowledge of the anatomy of the face and its fossæ. More clearly than any other book, it demonstrates, both in text and by illustration, that "typical anatomy is ideal anatomy." It is no exaggeration to say that it is delightfully free from the dogmatic; that its tone is essentially comparative, that it is, in short, thoroughly scientific in its attitude, from beginning to end, and leaves but little to be added to the intricate subjects with which it deals. The work is brilliantly illustrated by a good series of photographic reproductions, many of which are of section of the skull cut in every conceivable plane. Moreover, so much skill has been shown in the combining and arranging of the cuts that one can all but read the book without reference to the text. The chapter on anatomical variations is of peculiar interest and, together with one on impacted teeth, is of particular note to surgeons. On page 56 there is an illustration showing the three turbinate bones which surely should be in the hands of every student of anatomy. With unusual clearness it shows the comparative insignificance of the superior and middle bones.

Very naturally it is possible to pick a few flaws in such a work. Here, if at all, we find them where the author discusses the surgical significance of his findings. For example, on page 121, in speaking of the treatment of antral troubles, he endorses drainage via the nose rather than orally. This latter path is the one chosen by many surgeons and has advantages with which it does not seem to be credited by Dr. Cryer. But the book is an anatomy, not a surgery, and, as such it marks the turning of a big leaf in our knowledge of the subject.

PRACTICE OF MEDICINE. By Eminent Medical Specialists and Authorities. Edited by GEORGE ALEXANDER GIBSON, M.D., D.Sc., F.R.C.P. Edin., Physician to the Royal Infirmary, Edinburgh. In Two Volumes. J. B. Lippincott Company, Philadelphia.

THESE volumes represent a combination text-book of a type so prevalent in the United States. The editor says that the advances in every branch of medical science have been so great that a work written by several writers would most satisfactorily reflect modern English teaching and he has here given us such a volume.

From one standpoint the work is a very excellent one. It is convenient; it is conservative; the language is good, although there is great irregularity in the mode of presentation, some authors using the personal pronoun, and others the more acceptable text-book style. Each subject is treated in a sharp, practical manner and the student of medicine will gain from it a solid substratum of workable knowledge.

From the standpoint of the teacher or the progressive practitioner the work, taken as a whole, is a disappointment. In many branches the researches of recent years seem to have received no attention whatever. The old familiar groupings of disease are adhered to and newer ideas are not incorporated. The combination plan has not given a series of high class, authoritative and thoroughly modern descriptions of disease processes, but a group of comparatively superficial, quickly written and easily worded chapters.

Thus the chapters on diseases of metabolism, affections of the liver and the pancreas are extremely meager and unsatisfactory. Under diabetes no discussion is to be found of acid intoxication and its significance. The therapeutics of drugs is weak. The modern work on the chemistry of gout is not included; in fact, the newer pathological chemistry is conspicuous by its absence.

The chapters on the nervous system follow in the main the old classic of Gowers; a number of illustrations of the cranial nerve nuclei are included which are far from presenting the conditions as they have been given to neurologists by Bethe, Déjerine, Held, Van Gehuchten, Barker, and others.

If one should attempt to pass judgment on the book as a whole, it would be that, apart from certain chapters, the work is not up-to-date by some years.

Perhaps we, in America, do run after the strange gods "made in Germany" as well as in France, and give recognition to many Italian and Russian "Archives," yet a wider reading of the works of modern European workers would, we believe, have enabled the authors to make these volumes more valuable to the serious student.

A Treatise on the Acute Infectious Exanthemata. Including Variola, Rubeola, Scarlatina, Rubella, Varicella and Vaccinia, with Especial Reference to diagnosis and treatment. By William Thomas Corlett, M.D., L.R.C.P. Lond., Professor of Dermatology and Syphilology in Western Reserve University; Physician for Disease of the Skin to Lakeside Hospital; Consulting Dermatologist to Charity, St. Alexis and City Hospitals, Cleveland. F. A. Davis Company, Philadelphia.

The obstacles in the way of broad clinical study and bedside demonstration in such dangerous and highly communicable diseases as these render it hazardous and in many cases impracticable to impart sufficient instruction to undergraduates, so the combination of fever and a skin eruption is likely to fill the young practitioner with discomfiture, if not alarm. Who, then, can better help him than the dermatologist, to whom the skin manifestations are of paramount importance? These the author handles in more detail than is customary, though the other data also show a broad and thorough acquaintance with the literature, and personal familiarity with many types of these diseases. Indeed, his chapters on etiology, pathology, symptoms, complications, diagnosis and treatment will each merit careful perusal for their wealth of material and for the pleasing style in which they are written. The talks on anomalous cases and their diagnosis, particularly those of measles and varioloid, are indeed helpful. Not the least important are the opening chapter on the history of the exanthemata, the section on disinfection and the table in which are compared the chief features in the differential diagnosis of these acute eruptive diseases. The colored plates, though perhaps illustrating fairly well the lesions, have no artistic merit and convey to the mind the impression of crudeness and exaggeration. On the other hand, the photographic reproductions are excellent and typical, aptly illustrate the text, and have a real value as aids in diagnosis.

The Estivo-Autumnal Malarial Fevers. By Charles F. Craig, M.D. (Yale), Acting Assistant Surgeon U. S. Army; Pathologist and Bacteriologist to the U. S. Army General Hospital, Presidio of San Francisco, Cal. William Wood and Company, New York.

Since the return of our soldiers from the recent war, estivo-autumnal malaria has been so widely scattered throughout the country that an able exposition of this disease appeals to a much larger audience now than it did a few years ago. During the last two years so many peculiar cases with unusual trains of symptoms have proven to be estivo-autumnal malaria that an atypical form of this disease becomes very difficult to diagnose. The material for the proper study of this disease can be found only in the south, especially Cuba, and excellent opportunities have naturally been given to our army surgeons to investigate the disease. The life cycle of this form of malaria has now been entirely worked out and explanations of various unusual stages have been given in this book. The author had the good fortune to watch under the microscope the development of the crescent into a flagellated organism. At first the undeveloped crescent lay within a medium-sized corpuscle which finally melted away and from the crescent the flagellæ later broke forth. It was thus established (1) that crescents are developed within the red blood-cells, and (2) that the active flagellated parasite comes from the crescent. The proper methods for staining and examination of the blood, ignorance of which often leads to negative results, are also carefully given. The book is an interesting one which ought to be of considerable value in bringing this form of malaria more clearly before the profession and in making the diagnosis of the disease more easy and more certain.

Essentials of Obstetrics. By Charles J. Jewett, A.M., M.D., Sc.D., Professor of Obstetrics and Gynecology in the Long Island College Hospital and Obstetrician and Gynecologist to the Hospital; Charter Member of the Congrès Périodique International de Gynécologie et d' Obstetrique; Fellow of the British Gynecological Society; ex-Vice-President of the American Gynecological Society, ex-President of the New York Obstetrical Society, etc. Assisted by Harold F. Jewett, M.D. Lea Brothers & Co., New York and Philadelphia.

The more elaborate work of this author is so widely and favorably known that the student is especially fortunate in having the essential facts and principles of such a treatise placed before him in a concise and well-systematized manner. This smaller work is, however, not simply a quiz compend furnishing lists of information to be quickly learned and as quickly forgotten, but sufficiently describes the important features to make it interesting reading and valuable as a text-book for the student. A clear well-illustrated chapter is written upon the development of the embryo and the management of a normal case of labor occupies a long chapter containing many useful suggestions, but the author's methods for preventing tears of the perineum differ considerably from the generally accepted ideas. Some of the articles upon pathological conditions of pregnancy and labor are too brief to be of much value for the practising physician, but undoubtedly prove entirely sufficient to supply the needs of the student for whom the book is intended.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Clinical Hematology. By Dr. John C. DaCosta, Jr. 8vo, 474 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

A Manual of Venereal and Sexual Diseases. By Drs. Wm. A. Hackett and N. E. Aronstam. Demi 8vo, 308 pages. G. P. Engelhard & Company, Chicago.

Text-Book of Histology. By Dr. Phillipp Stöhr. P. Blakiston's Son & Co., Philadelphia.

Manual of Physical Diagnosis for the Use of Students and Physicians. By Dr. James Tyson. Fourth Edition. Demi 8vo, 298 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

Transactions of the American Gynecological Society. Volume 26, for the year 1901. J. Riddle Goffe, M.D., Secretary. Philadelphia.

ORIGINAL ARTICLES.

ON THE VALUE TO THE PHYSICIAN OF MODERN METHODS OF DIAGNOSIS.[1]

BY HENRY L. ELSNER, M.D.,

OF SYRACUSE;

PROFESSOR OF SCIENCE AND ART OF MEDICINE AND CLINICAL MEDICINE, SYRACUSE UNIVERSITY; PHYSICIAN TO ST. JOSEPH'S HOSPITAL; CONSULTING PHYSICIAN TO THE HOSPITAL FOR WOMEN AND CHILDREN.

ON THIS occasion I wish once more to express to you my thorough appreciation of the great honor which my election to the presidency of the Medical Society of the State of New York implied and to thank you heartily for this proud distinction.

The development of medical science has been so rapid that to those who have been in practice twenty or even fifteen years, who have not kept pace with the advances and the scientific movement, the language of the medicine of to-day is almost unintelligible. Indeed, medicine has been metamorphosed from an art into a science, to the everlasting credit of an unselfish profession and to the benefit of mankind.

Rational medicine requires for its successful practice a scientific foundation. It is not long since our methods of investigation were crude and faulty; instruments of precision were wanting and the many refinements of diagnosis which we now possess were either undiscovered or the few in use were to be found only in the larger universities. It gradually became evident, however, that to complete the education of the physician it was necessary to establish the laboratory (that true workshop of the physician) where he might study the conditions which exist in health; learn to appreciate the changes wrought by disease; gather lessons from the thorough study of physiological chemistry, and record many facts concerning the modification of perverted functions by the application of remedies. Without these object lessons many of the astounding advances of modern medicine could not have been made. By the aid of these, medicine has made greater progress during the past three decades than had previously been made in as many centuries.

The scientist must of necessity be a revolutionist. All things he must prove for himself. Richet has truly said, "By experiment and by science, medicine is compelled to march forward." This is as true to-day as it was in the time of Harvey and should prompt us to encourage in all fields of medicine, wherever permissible, original, painstaking experiment and the conscientious application of positive conclusions to the recognition and treatment of disease.

Unalterable and earnest in the belief that modern methods of diagnosis have proven themselves of the greatest advantage to the physician in the study of disease, and with a conviction deeply grounded, much against my will, that only a minority of the medical profession has adopted these refinements by the use of which medicine in its science becomes more and more exact, I have concluded on this occasion to address you "On the Value to the Physician of Modern Methods of Diagnosis."

The profession, as organized in our Society, has always represented a progressive element in medicine; has demonstrated its willingness to enlarge and enrich its field of usefulness and influence; has striven to disseminate knowledge far beyond the limits of our own State; and it is because of this encouraging past and the promising present which cements the past and the future that I bring this subject to your notice in order that our influence may be exerted in behalf of methods in diagnosis which rest on a scientific foundation and which prove, when impartially reviewed, to be of inestimable value to the suffering.

We are not to rest content with the uncertain methods of our forefathers, which seemed to them, as they seem to many to-day, to unearth the entire truth, but with Lessing we must proclaim, "Not the bare truth which everybody possesses, or thinks he possesses, but the earnest endeavor which he has made to understand the whole truth—to get at the foundation of it—makes the worth of a man. For it is not through its possession, but rather through the search for the truth that his powers are enlarged, which alone make for his growth toward perfection. Possession makes him quiet, indolent, proud." Ours is a profession which can ill afford to be satisfied with possession which makes it innocuous and proud. Ours is the task of blasting in the quarries of the unknown, where are hidden innumerable precious truths awaiting development. Thus may our art "gain the reach and certitude of sway over disease which we all yearn for it to possess."

Sir Michael Foster has recently said, "The phenomena of disease, being phenomena of living beings, present themselves in most, if not in all cases, as problems, as mixed problems of physics, chemistry, and biology, to be grappled with by the doctor as they are grappled with by the physicist, the chemist, and the biologist." To this quotation, I add the words of our own philosopher and pathologist, Welsh, recently given to the profession at the Virchow dinner: "General pathology must call to its service not only morbid anatomy, but also experimental and clinical medicine;

[1] President's address delivered at the ninety-sixth meeting of the Medical Society of the State of New York, Albany, Jan. 28-30, 1902.

nor is practical medicine to be founded upon pathological anatomy and general pathology alone, important as they are to the physician in many ways. Clinical medicine, as well as every other department of medicine, must be investigated by itself, deriving, as should every science, all the aid it can from allied sciences."

Our appreciation of clinical diagnosis by means of microscopic and chemical methods is well demonstrated by the hearty welcome with which the original work of Von Jaksch and later the volume of Simon's, both on clinical diagnosis based on newer methods, were received by the progressive internists. We were eager for more exact knowledge—for science to aid us in our art. The statement by Simon, that "Diagnosis is now the password in medical science," needs to be realized by many who continue satisfied with the uncertain methods of the past. The value of the application of the knowledge of physiological chemistry to the recognition of disease is splendidly illustrated by the certainty with which many diseases of the stomach and intestines are thereby recognized. Here I may be permitted to quote from a former address: "With the discovery of free hydrochloric acid in the gastric mucus by Prout in 1824, and the demonstration of pepsin by Schwann in 1836, the first data for an ultimate and more thorough understanding of the physiological and chemical functions of the stomach were given. These discoveries, with those of Reaumur and Spallanzani, formed the foundation upon which ultimate gastric pathology was to rest, and upon which a structure has been erected to which modern medicine points with just pride.

" 'The way to pathology is through physiology,' says Ewald, and the more we deal with this subject, the firmer is the truth of that statement impressed upon our minds. It is not the study of the peptonizing function alone which claims our attention, but it is the proper understanding of the entire work which is performed in this human laboratory, including a large part of the alimentary canal, and a thorough appreciation of the relations which each function bears to the others, that make a rational anatomical diagnosis and indications for treatment possible and in many cases positive."

When Kussmaul in 1869 first used the stomach-pump and tube in the treatment of disease, Liebermeister correctly prophesied that this maneuver would probably mark an epoch in gastric pathology and therapy. When Leube in 1871 first recommended the stomach-tube for purposes of diagnoses, he cleared the way for the ready diagnosis of stomach disease. Without the methods evolved from Leubeg's original innovation, gastric diagnosis would soon fall and the treatment of stomach disease would once more become as unscientific as of yore.

The diagnostic value of the absence or diminution of free HCl in the stomach secretion, associated more particularly with piloric cancer and ultimate dilatation, was first systematically investigated by R. von den Velden at Kussmaul's clinic in Strassburg. Golding Bird called attention to this fact in 1842 and it seems strange that this information was ignored by the profession for diagnostic purposes during so many years.

I found in my investigations of gastric cancer, reported in 1893, in one hundred and twenty tests, free HCl absent in 92.7 per cent. and present (as a rule feebly) in 7.3 per cent.; from a larger number of cases since studied, material change in these figures is not justified.

The diagnosis of cancer of the stomach from the absence or presence of free HCl *alone* ought never to be made, but, associated with other symptoms leaning toward malignancy, we may assume with considerable certainty that the demonstration of the presence of HCl argues against the existence of cancer. The cases, according to Ewald, "in which there is a positive reaction to the carefully-applied tests are so rare that they have very little bearing on the question." Since the introduction of these chemical tests for the recognition of diseases of the stomach, we have learned much which is of value relative to blood-changes in these and other diseases. Thus, in some cases of latent or progressive cancer of the stomach, atrophy of the gastric follicles and pernicious anemia or other diseases associated with cachexia, stomach symptoms, and blood-changes, the combined results of gastric tests with the blood-examinations, *repeatedly* made, give facts which we must possess to clear the horizon and justify positive diagnosis.

Henry's observation showing that the reduction of red blood-corpuscles in cancer of the stomach does not keep pace with the cachexia, while in pernicious anemia the cachexia does not keep pace with the reduction of red blood-corpuscles, has been corroborated many times and is of great diagnostic value.

For the surgeon the knowledge gained by our new methods in stomach disease is strongly confirmatory. With a growing experience we are justified in entertaining for the future a well-founded hope of recognizing malignant disease of the stomach early, when as the surgeon's helpmates we shall save or prolong many lives in comparative comfort. By these methods of diagnosis the dietetics and therapeutics of gastro-intestinal diseases have been placed upon a more solid and scientific basis. The satisfaction experienced by the physician in outlining a diet which he knows will positively find a suitable reception and ultimate assimilation must be sufficient recompense for the time occupied in studying the individual case.

Time will not permit the rehearsal of profitable experiences in this field. The recognition by our positive methods of qualitative and quantitative changes in the secretory function of the stomach has ended the suffering of many chronic invalids. The recognition of hyperacidity and hypersecretion has relieved many unfortunate sufferers from uncontrollable pain, waning strength and wasting muscle, with rebellious

stomach symptoms. Scientific diagnosis in these cases, followed by rational treatment, yields brilliant results. No physician can do justice to himself or to his charge who is unable, when the case demands it, to apply the simple methods which without great labor or loss of time make clear to him the working ability of the stomach in its secretory, motor and absorptive parts.

No one who has worked in the broad field of medicine, unless finally biased by narrow and special practice, contends that in all diseases of the stomach we need the test-meal and the knowledge gained by its chemical examination for the recognition of disease. We shall always meet a large number of cases, however, with uncertain symptoms, with strong indications of disturbed gastric function, cases with features of malignancy, though without positive physical signs; cases in which the question of the benign or the malignant nature of the underlying process needs prompt recognition, in which we shall be able to add a strong link by the correct interpretation of data gained by the methods founded upon our knowledge of physiological chemistry.

In this connection I must call your attention to the great value of inflation of the stomach with air or carbonic acid gas. In office practice we often gain knowledge of the relative size and position of the stomach; of its relation to the neighboring organs; of its walls, as well as the resistance of these, by the administration of a Seidlitz powder, each part separately, to allow the escape of gas in the stomach to distend it. More satisfactory, in cases in which this maneuver fails, is the inflation with air through the stomach-tube. The failure to inflate the stomach by these means, with associated symptoms of malignancy, and the absence of tumor and free HCl would lead to a suspicion of infiltrating disease of the stomach-wall. In some cases adhesions to the surrounding organs have thus been recognized, while in a case of ulcerating cancer it was found that the adherent transverse colon was readily distended with the tube in the stomach, because of communication which existed between these viscera as the result of ulcerative changes.

The distention of the large intestine with air is frequently of great value in the localization of abdominal diseases; particularly useful in the recognition of renal growths in which the distended gut is found anterior to the growth. These methods are too rarely used and will not be discarded when fairly tested. The precipitation by centrifugal force of cellular elements from the stomach-contents, with microscopic and bacteriologic examinations, will often prove of great therapeutic and diagnostic value.

In connection with the diagnosis of syphilitic diseases, a fact which has been too often overlooked and which is rarely mentioned is the tolerance for the iodides in specific cases of ulcer and gastritis and the ready relief experienced. Under ordinary circumstances the symptoms of these patients are almost immediately aggravated.

The application of centrifugal force to clinical medicine is of recent date. Steinbeck of Stockholm, a medical student, first described the use of the centrifuge for the precipitation of sediments from urine, sputum, and other pathological fluids. Litten at the Congress of Internal Medicine in 1891 made a strong argument in favor of its use; Von Jaksch described the positive advantage of the combination of the centrifuge and Biedert's method in cases in which he was unable to find bacilli after patient search. Freeborn of New York in 1891 demonstrated a home-made machine capable of nine hundred and fifty revolutions per minute. Gerster and Sondern followed with contributions on this subject and in 1894 Elsner and Hawley, after a considerable experience with the instrument, dilated on the clinical value of the centrifuge.

Experience with the centrifuge has proved it to be of inestimable value. It is one of the few aids to diagnosis which have been generally adopted and to-day there is practically no laboratory or hospital in which it is not found. The time gained by centrifugalizing urine is of great advantage, when an unaltered urine is desired (fermentation not having taken place); the early precipitate shows epithelial casts and other structures before changes in shape, size and contour occur, and these without bacterial contamination. By the use of the centrifuge, insoluble and suspended elements are precipitated.

Blood may be precipitated when present in such small proportion that no other method would show it. It is invaluable to the insurance examiner in aiding to discover the underlying condition in cases of so-called transitory cyclic or of puzzling permanent albuminuria. It is our most reliable aid in detecting early primary genito-urinary tuberculosis. It precipitates small quantities of albumin with picric acid and makes possible the immediate application of Esbach's test, thus saving twenty-four hours.

The bacteriological examination of serous exudates and other pathological fluids is expedited by its use, as is also the examination of sputum for tubercle bacilli when they are present in small numbers. The writer found that in twenty-one per cent. of urine analyses, the centrifuge yielded results which led to greater accuracy in diagnosis than could have been otherwise obtained.

In doubtful cases of renal calculosis, the methods of Kelly, including the distention of the kidney and its pelvis with water, after his improved maneuver, gives information which cannot be obtained without exploratory operation. The added evidence furnished by the X-ray examination and the skiagraph will often furnish proof which justifies accurate and scientific diagnoses, though the clinical history may be meager and unsatisfactory. These and similar methods, with painstaking bedside study, may arouse suspicions which must finally lead to positive conclusions.

The birth of a new science, hematology, founded upon accurately-interpreted data, has added great pleasure and material profit to the

study of many conditions, formerly puzzling in their differentiation and unsatisfactory in their treatment. No diagnostic methods in medicine give more conclusive evidence or offer more uncontrovertible pictures than are revealed by those which we to-day include in our examinations of the blood. When I hold that these methods have not only been profitable, but have given the diagnostician genuine pleasure, I speak without exaggeration.

It is not the object of the evenly-balanced physician to replace the knowledge gained at the bedside by laboratory findings, or to limit diagnosis by considering only facts made positive by microscopical examination and staining of the blood, but to *add* the exact knowledge which was unattainable before the advent of hematology. Let him who has never relied upon blood-examination for assistance in diagnosis work but a short time in this field, and he will unfold a chapter to which he will revert for information and upon which he will learn to place great reliance as he becomes more and more conversant and expert in technic. Blood-examination means much more than would appear on the surface to those who are unacquainted with hematological methods. From a narrow conception of the true significance of the anemias, we have broadened the field until we hold without fear of successful contradiction that the positive diagnosis of the simplest form cannot be made without the aid of data obtainable by blood-examination.

Clinically the picture of a grave anemia, nonmalignant, is often identical with that of pernicious anemia. Pernicious anemia may in some of its stages simulate exactly in subjective symptoms and in many of its objective features a true leucemia, while Hodgkin's disease may present symptoms not unlike malignant disease, lymphatic or mixed leucemia. The missing link in the differential diagnosis can be furnished only by laboratory examination of the blood.

Without the quantitative test for hemoglobin, we would often fail in our differentiation of the anemias, while our treatment would continue to be irrational.

Differential blood-counts and staining methods give data which justify the positive differentiation of the various forms of anemia known as leucemia. Thus, we have learned to recognize the pathognomonic lymphocyte of lymphatic leucemia and the myelocyte of the myelogenous or splenomyelogenous variety of the disease.

Who shall be able to compute for the profession the gain which has accrued from our ability to diagnose malaria from the presence in the blood of its protozoon? Our ready method of demonstrating the organism of malaria has made positive the nature of many most difficult and troublesome conditions. Add to this the readiness with which, after the method of Sittman, we recognize bacterial contamination of the blood and you have included methods by which medicine has become more exact and satisfactory. In many epidemics we meet continued fevers without characteristic symptoms of typhoid, which can be diagnosticated only by the systematic use of the Widal agglutination test. The percentage of failures is relatively small, while the positive information, so much needed in doubtful cases, is often, though not always, obtained. Absence of leucocytosis or a diminution below the normal of leucocytes with fever, with the absence of other objective features, has often justified the diagnosis of typhoid before a positive Widal test was obtainable. The presence of leucocytosis with chills and fever or with continued fever, with or without local symptoms, has often led to conclusions which have been life-saving in their effect. Sudden and persistent leucocytosis in typhoid fever and in other conditions not usually associated with polymorphonuclear leucocytic increase, points to complications the nature of which may be surmised with great certainty when the result of the blood-examination is considered with the associated subjective and objective symptoms.

The revelations of a leucocyte-count in a case recently seen in which irregular fever and chills followed dysentery, without more than a slight tenderness in the right hypochondrium with slightly-enlarged liver, furnished the information which made pus accumulation probable and justified exploration. An abscess of the liver was found.

Puzzling cases in which tuberculous diseases require differentiation are often cleared up by a count of leucocytes. This method of differentiation is one which we will often use and, unless we have mixed infection with tuberculosis, the absence of leucocytosis may be considered an important factor in diagnosis. Thus, in tuberculous peritonitis the leucocyte-count is not materially increased. Leucocytosis with brain symptoms argues in favor of meningitis, non-tuberculous.

Much has been written recently on the condition of the blood in surgical disease, particularly in appendicitis. In connection with this disease we must not fail to give an existing leucocytosis the prominence which it deserves. To depend upon the results of the blood-examination, without giving to other symptoms in a suspected case of appendicitis their proper import, would lead to unpardonable error.

The diagnosis of *trichina spiralis* may be and has been corroborated in doubtful cases by the presence of eosinophilia. Eosinophilic increase may become an aid in the recognition of scarlet fever when other data are wanting or meager.

The detection of indican with or without leucocytosis gives information of value in occasional doubtful intestinal and abdominal diseases.

It has been said that the time occupied in making blood-examinations is out of all proportion to the knowledge acquired—an unjust and untrue charge. To gain exact information is our aim at any expense of time, but fortunately a thorough blood-examination can be completed in less than one and one-half hours, while in the majority of cases, with our newer methods and better technic, one-half that time will suffice to give the informa-

tion needed. The successful and busy physician ought to be willing to relegate this work to those less occupied; he will always be able to find trained assistants to complete this work for him. The simple and rapid methods of staining malarial and other blood-films without fixation, after the method of Romanowsky, and with the Jenner panoptic stain, reduce materially the time necessary for gaining satisfactory results.

The bacteriological diagnosis of certain diseases has become a matter of routine with the scientific worker. To the bacteriologist we look for the solution of many important problems in the prevention and recognition of disease. The number of lives annually saved by the application of bacteriological methods to the diagnosis of disease cannot be estimated.

When we consider the advantage of the bacteriological examination of the blood, including culture experiments, we are led into a broad field in which the practising physician cannot do more than accept the knowledge gained from the well-equipped laboratory over which special workers must always preside.

We have not received the encouragement which we deserve from the State in our efforts to prevent and diagnose disease. The policy of the State in this direction has been niggardly and short-sighted. Every section of the State should have a well-equipped laboratory in which thorough bacteriological work may be done to give the aid to the profession which for public safety is often promptly needed, and by which many difficult questions can be definitely settled. Thus, I have found during the past year counties in which there were no facilities for making cultures in cases of diphtheria, or for the application of bacteriological methods to the recognition or treatment of disease. Such faulty policy can only end in disaster and useless sacrifice of precious lives. I fear that many in our profession, as well as our legislators, have failed to appreciate what a leading part microscopy and bacteriology play, for an improved diagnosis is but a small portion of the gain to be derived from a scientific study of the causes of disease. "A new direction has been given to treatment."

The enormous advantages of serum diagnosis were well illustrated during the Spanish war, when the fevers prevalent among the American soldiers in Cuba and Porto Rico were claiming so many victims, and the differential diagnosis of typhoid malaria and the dysenteries was of such transcendent importance. The blood of ninety-five per cent. of the typhoids showed a positive serum reaction, the malarias were easily recognized by the characteristic protozoa, while the dysenteries gave no positive blood-picture.

Cases of typhoid associated with jaundice are mentioned by Cabot in which the diagnosis of yellow fever was eliminated by the immediate typhoid serum reaction. Cabot says, and it is true of serum diagnosis, "The whole process can easily and safely be carried out by the physician in his office without any laboratory facilities and without half the skill or labor necessary to examine the urinary sediments."

Much has been written during the last few years on the advantage of lumbar puncture in doubtful cases of brain disease, particularly in tuberculous meningitis. Microscopical examination of the fluid has often been negative. Langer sought to aid diagnosis by incubating the fluid withdrawn, but the patients died, as a rule, before conclusions were reached.

For animal experimentation large quantities of fluid are required, even for intraperitoneal injection, and positive results are too long postponed. It is doubtful whether in case of failure to demonstrate microscopically the presence of tubercle bacilli in the fluid withdrawn, we shall succeed by experiment of any kind in establishing a diagnosis with sufficient rapidity to be of any value to the physician.

It has been found that sugar is usually present in the meningeal fluid in cases of brain tumor, while in tuberculous meningitis it is absent as a rule. It will be preferable to depend on the ophthalmoscope in these cases without the puncture. Lumbar puncture in the hands of the inexperienced or uncleanly is not without its dangers. It is not at all likely that it will ever be adopted by the general profession for diagnostic purposes; indeed, in the majority of cases we are not dependent upon the information which it has been supposed by some to convey.

In occasional cases the diagnosis of malignant disease may be strengthened by the examination of serous effusions and tissue removed after some one of the improved methods.

Cancer-cells are no longer considered characteristic. Dock has shown that similar cells are found in cancerous, tuberculous and other effusions. The presence of many cells in serous effusions showing mitosis, either typical or atypical in type, is strongly suggestive of malignant growth. Centrifugalized specimens may, however, be examined for evidences of mitosis with negative result. The specific gravity of cancerous effusion is low, that of tuberculous higher, varying between 1020 and 1028. The presence of a large amount of blood has in several cases of cancerous effusions raised the specific gravity to 1020 or even 1022.

Simon says, "Clinically, it is frequently difficult to distinguish between transudates and exudates, and large ovarian, pancreatic, and hydatid cysts, as well as cystic kidneys, may at times be mistaken for ascites. In such cases a careful chemical and microscopical examination of the fluid in question may be of decided value. Very frequently, moreover, it is possible only in this manner to determine the true nature of the disease, and the importance of freely using the trocar and the aspirating-needle in diagnosis cannot be too frequently advocated."

The use of the Roentgen rays in medicine seems almost uncanny. It is doubtful whether with our present technic we gain many pictures which justify positive conclusions in the study

of internal diseases. The greater reliance must still be placed on associated physical signs and subjective symptoms. Certain it is that a correct interpretation of the skiagraph requires great experience and the production of the shadow must always be relegated to those whose practices are limited and who have infinite time and patience to give to this work. I know of no field in which greater perseverance and attention to detail are needed.

We have received valuable aid from X-ray examinations in diseases of the lungs and heart, especially when an accurate knowledge as to the size and movement of those organs was needed. The diagnosis of intrathoracic growths and aneurisms has been strengthened by the fluoroscope and skiagraph, without ignoring associated clinical manifestations. This method of inspection has been of greater advantage to the surgeon than to the physician, but to deny its value in medicine would be absurd and unjust. Changes in the bone, about the joints, and gouty deposits have been satisfactorily demonstrated. Dense foreign bodies in internal organs, such as calculi, are very often demonstrated by the Roentgen rays. Porous calculi have escaped detection in several cases examined by this method. If the negative picture had been depended upon, one case recently seen, in which there were over 500 calculi in the gall-bladder, would have remained unoperated upon.

Skiagraphy may be said to be in its infancy, but we are encouraged by the labors of Williams, Leonard, Stubbert and others, to hope for great assistance in the future from the use of the Roentgen rays in medicine. The recent introduction of an apparatus for giving stereoscopic vision by the X-ray is believed by some to add materially to the practical value in medicine and surgery of this method of examination. The usual silhouette effect is replaced by a picture which stands out distinctly, showing the space relations of the object viewed.

We are not to be discouraged by the fact that radiographs which seem unsatisfactory to the majority of ordinary observers are readily interpreted by the expert, for, in cases in which we must place considerable dependence upon these pictures as giving evidence of pathological change, we shall give the opinion of the X-ray expert the importance which it deserves, remembering always that we have received but a link and to strengthen the chain requires the thorough application of other confirmatory methods.

The scientific diagnosis of many diseases of the nervous system has been materially aided by our knowledge of the electrical reactions of the different tissues in health and disease. To those only who have a thorough conception of the newer anatomy and pathology of the nervous system will electricity give any assistance in diagnosis. Here, as in the localization of central and peripheral nervous lesions, physiological knowledge remains the ground-work upon which diagnosis must be builded

Bennett has, after patient clinical observation in this field of diagnosis, demonstrated the truth of the statement that "Like all of our methods of physical diagnosis, electricity must not be depended upon as the sole means by which we are to arrive at a just conclusion in investigating the nature of disease. It is only one of the aids we employ, but which in conjunction with other facts and observations is a most powerful auxiliary." There are a sufficient number of instances in which electricity offers data for diagnosis which cannot be obtained from any other source and for this reason the general practitioner, as well as the specialist, must acquaint himself with the method of its application and must possess the underlying knowledge which makes rational conclusion possible. Though electricity may not be absolutely necessary for the diagnosis of the various paralyses it remains the means of giving it "a facility and precision which has become indispensable to the neurologist." Electric reactions, associated with a thorough study of the deep and superficial reflexes, lead to the interpretation of phenomena upon which depend localization and diagnosis in many puzzling conditions.

An instrument of precision too little employed by the general practitioners is the ophthalmoscope, for the introduction of which the memory of Von Helmholz will always be revered. If the information obtained from its use were limited to the eye, we would not consider its value on this occasion; it gives information regarding the existence and nature of pathological conditions elsewhere than in the eye which is often obtainable in no other way.

Gowers, in his classic work on Medical Ophthalmoscopy, says, "This information depends upon the circumstances that we have under observation: (1) The termination of an artery and the commencement of a vein, with blood circulating in each; (2) the termination of a nerve, which, from its close proximity to the brain and from other circumstances, undergoes significant changes in various diseases of the brain and in affections of other parts of the nervous system; (3) a nervous structure, the retina, and a vascular structure, the choroid, which also suffer in a peculiar way in many general diseases."

We do not contend that the general practitioner must of necessity become an expert in the use of the ophthalmoscope, but we believe that he must depend upon its revelations, if he would early recognize certain diseases of the brain, arterial degeneration and renal complications. Time does not allow on this occasion of an extensive argument in favor of the more frequent use of the ophthalmoscope by the physician; many cases might be taken from the records of those who have learned to use this instrument in general medical practice, which justify the great satisfaction with which its use is continued. We have only to refer to the significance of optic neuritis with brain symptoms, however vague, the presence of choroidal tuberculosis in advance of other positive symptoms, the presence of albuminuric

retinitis in cases of non-albuminuric nephritis, and the presence of retinitis and changed vessels in comparatively young subjects with transitory albuminuria and tube-casts, to show the value of the ophthalmoscope to the every-day doctor.

Those who for any reason are unable to refer these cases to special workers in this field should educate themselves by post-graduate study in the use of the ophthalmoscope for the recognition of the grosser pathologic changes in the eye.

In the preparation of this address the fact is appreciated that reference has been made only to a few of the newer methods upon which the profession is to-day leaning as aids in diagnosis. Limited time does not permit the consideration of many of the methods which are of undoubted value as adjuvants in the recognition of disease. That which I wish to emphasize is the importance of working systematically and scientifically, however busy we may be in our practices.

It is no secret that the charge has been made that too many patients in this country are often ignorantly and incompetently treated, and our medical schools and system of medical education are held responsible for this state of affairs. We must admit that we too often fail to stimulate the "scientific sense"; men are not educated to work systematically. Raise as high as you can the requirements for admission into the profession, gain the best timber possible, which will always include a majority receptive and earnest, and these serious charges will be less frequently made. We shall never be able to impress all with the enormous responsibility under which many almost stagger in medicine.

Many agencies have influenced American medicine. Whether these originated from communion with Louis, Laennec, Trousseau or Charcot in France; whether they were led by the Berlin school, the immortal Schoenlein, Traube, or Virchow, and their followers; were founded upon the methods of the Vienna school from which radiated the benign influence of Bamberger, Duschek, Skoda and a score of others, or were the products of our own enlightened masters of medicine—and we have had many—each had a scientific fundament and each vied with the other in unearthing new truths to be applied to the recognition of disease and its treatment.

The clinical medicine of the past may with reason be compared with a rude and hardy plant, now grown in spite of neglect to a colossal tree with innumerable branches, richly laden with fruit, its roots reaching far into the fertile soil for nutriment. This soil must be nurtured and sustained, else the tree will fade and die. The new must become an integral part of our being; the new of to-day is often enriched by the new of yesterday. True it is that "stagnation is something more than death." The physician of to-day has countless advantages over his forebears; his training makes him more enlightened, he has been forced to equip himself for life's work. The advantages offered for the thorough and scientific study of disease were never before equaled in this or any other country.

A generous public, by the free giving of material aid, encourages the solution of scientific problems related to disease and its prevention by scientific methods. In return it has a right to demand the product of our best, our most conscientious efforts. Are we not also prompted by selfish motives to work scientifically? Our only safeguard against quackery is "continued recurrence to the scientific basis on which the practice of medicine rests." We must gain exact knowledge in order to derive satisfaction from our practice. Even with increasing knowledge the layman's demands may in many cases be far beyond our ability to supply.

We can ill afford to encourage iconoclasts in medicine. Fortunate for us that we have no Paracelsus—a badly-balanced genius—a dangerous revolutionist at work to reject all that has been taught because of a pronounced taste for a single science. There will always be extremists against whom the evenly-balanced must array themselves. The application of modern methods in the diagnosis of disease must always remain supplementary to bedside study, but no one who has taken advantage of laboratory methods will deny that by laboratory study much may be learned of the greatest scientific and practical importance without which we would be poor indeed. The practical diagnostician will not be narrowed by the association of laboratory methods with clinical data; he will not become theoretical, but more practical; he will become a more acute and cautious observer because of this training; he will "acquire knowledge at first hand" and make fewer hurried diagnoses; he will be prompted to do more original work.

There are those who, in spite of the fact that we are encouraged in all educational matters to develop the observant sense, continue to decry all laboratory and scientific methods. The scientist is charged with being a dreamer and impractical. "There are some, indeed, who would tell you that the scientific man is ill fated for anything but science; that he cannot be punctual, business-like, a plain speaker, pious, or I know not what else." . . . "It would be difficult to find greater nonsense in any of the books or journals on a modern bookstall." . . . "There is nothing that a man may not be at the same time that he is scientific." (Paget.)

Failures in practice are by no means limited to the scientific. This fact requires no extended argument. Did Schoenlin's practical work in Berlin suffer because of his scientific attainments or because he became the pioneer in Germany in the introduction of physiological methods, the microscope and chemical analysis, in the study of his clinical material?

Haller had made the attempt one hundred years before, but the scientific fundament supplied by pathological anatomy was wanting. Hippocrates

auscultated, and Anenbrugger one hundred years before Laennec attempted to introduce percussion as a diagnostic agent. These attempts bore no fruit; pathological anatomy was needed to make clear the meaning of physical signs. It is by no means to be considered an accident that, among the greatest advances in medicine made during the century just closed, both pathological anatomy and auscultation were introduced into the clinic by the same clear mind, Laennec. He is one of the greatest physicians in history. Allbutt has said, "He deserves to stand by the side of Hippocrates, Galen, Harvey and Suydenham. His work was a revelation of the morbid anatomy of the internal organs during the life of the patient."

The physician who is truly successful in practice must depend in a great degree upon the good opinion of his fellow-practitioners. Laymen have not the positive means of gauging our ability which those possess who are fitted to judge.

Nothing commends itself to the professional mind as does the thorough scientific investigation of individual cases. Certainly there are among those who have no medical education some who judge reasonably of the physician's worth; but the number of these is few. Of the majority we may say they are the most ignorant who are most positive and loudest in their praise or denunciation, and these are often the most influential.

Herbert Spencer has well said, "Had we time to master all subjects, we need not be particular."

> "Could a man be secure
> That his days would endure
> As of old, for a thousand long years,
> What things might he know!
> What deeds might he do!
> And all without hurry or care."

Bearing in mind our limited time for acquisition and action, the question which is of such transcendent moment is whether the methods recently introduced are of sufficient benefit in the study of disease to claim our attention and time. We must determine, in other words, "the relative values of knowledge." If we consider the relative worth of these methods to the clinician from an unbiased standpoint, we must conclude in favor of the adequateness of the advantages. There is certainly a proportion between the required labor and the probable benefit. The young man needs the knowledge and training which the thorough study of disease develops, while those who have grown old in the treadmill must take advantage of modern methods and ideas to retain their standing in the profession.

Sir James Paget, in his Memoirs recently published, writing on the "Ways into Practice" and the "Various Ways out of Practice," speaks candidly of the conditions which affect success and invite retrogression. Between the lines one can read the thoughts of this clear-minded gentleman-physician and the appreciation by him of the importance to the honest worker of receiving, after a sufficient period of probation, the methods which were included in the armamentarium of his juniors and pupils.

To those who are practising at a distance from centers where men are devoting themselves to the accurate methods in medicine, a word of warning may not be misplaced at this time. Your influence will not endure if you persist in ignoring methods which have been tried and found useful. You will finally hold only a remnant of your present clientèle. In spite of the fact that the public has never been more credulous or more ready to encourage quackery, the services demanded from the physician were never before expected to be of so high an order. His search must always be after the ends of science. "The real and legitimate goal of all sciences is the endowment of human life with new inventions and riches." The individual has a right to demand of his physician accurate recording of all facts relating to his condition with a painstaking investigation of every detail which the case offers, by *every method needed for accurate observation and ultimate diagnosis.* Believing that modern methods of diagnosis lead to the trustworthy interpretation of symptoms, with a firm belief in the superior ability of those who have adopted these methods, the lay world is fast removing its former prejudices aganst hospitals in which medicine and surgery are practised rationally. The consulting-rooms of those who are known to employ most thorough methods are filled with all classes of clients. There is a feeling abroad which calls for thoroughness from those charged with the recognition and treatment of disease.

The period has not yet been reached when we can truthfully deny that our art is in advance of scientific direction and explanation. Now as always we need common sense, as well as knowledge, with ready decision and resourcefulness. These no college or teacher can supply. We must never allow our critical faculties to exceed the practical. It has been truly said that "practice without scientific reëdification soon degenerates into stereotyped and sterile routine." No amount of extra labor bestowed on the study of disease will prove irksome to him who possesses the true scientific spirit; on the other hand, the consciousness of a duty thoroughly and consistently performed will prove an ample reward.

Out of the clinical laboratory "the new medicine is to come—the medicine which, penetrating into the intimate processes of Nature, learns to turn Nature to her own correction—the clinical laboratory is to be the scene of the study of the origins of disease."

"A life full of work and labor is no burden, but a boon, an enjoyment." This served as the text of Virchow's original thesis. His life has been sweetened by the conscientious and scientific application of his great powers, and it is this spirit which will continue to inspire the physician.

The moral force of scientific methods in medicine is the greatest factor in modern medical practice.

NOTE ON THE GLYCOSURIA FOLLOWING EXPERIMENTAL INJECTIONS OF ADRENALIN.*

BY C. A. HERTER, M.D.,
PROFESSOR OF PATHOLOGICAL CHEMISTRY, UNIVERSITY AND BELLEVUE MEDICAL SCHOOL,
AND
A. N. RICHARDS, PH.D.,
OF NEW YORK;
RESEARCH SCHOLAR OF THE ROCKEFELLER INSTITUTE.

IT is the object of this communication to call attention to the fact that when a considerable quantity of adrenalin (Takamine) is injected into the peritoneal cavity of a normal dog there follows a rapid and usually considerable excretion of dextrose with the urine. This fact was noted in the course of a research upon the functions of the pancreas, which is being carried on by the writers under the auspices of the Rockefeller Institute for Medical Research.

Apparently the first observations on the influence of the suprarenal gland upon carbohydrate metabolism were those of Blum[1] who found that the urine of animals subcutaneously injected with considerable quantities of an extract of fresh suprarenal gland regularly contained sugar, even when the diet of the animals (chiefly dogs) had been free from carbohydrates. The highest percentage of dextrose observed was 3.8 per cent.; usually the concentration of sugar in the urine was much lower.

The discovery of Blum has recently been confirmed by G. Luelzer[2] and, in this country, by Croftan.[3] The latter writer reaches the conclusion that the glycosuria observed by him in rabbits and dogs depends on the action of a diastatic ferment in the suprarenal gland which converts the glycogen of the liver into sugar.

The observations made by us on the action of adrenalin in producing glycosuria are strongly opposed to the idea that the suprarenal glycosuria is connected with a diastatic ferment contained in this organ. Further reference will be made to this point.

Two very recent publications[4] relating to the chemistry and pharmacology of adrenalin fail to make any reference to the ability of this preparation to induce glycosuria and it seems fair to infer that this action of adrenalin has not heretofore been noted. The omission is the more noticeable as one of these papers is by Takamine (to whose ingenuity we owe adrenalin) whom one may presume to be fully familiar with the investigations that have been made on the properties of the extract.

The following are brief extracts from the protocols of our experiments:

Experiment I.—A small terrier (about 16 lbs.) received 6 c.c. of a 1-1,000 adrenalin solution (Takamine) in the peritoneal cavity. During the following two hours there were repeated vomiting and great excitement which gave way to prostration and unsteady gait. Urine previous to injection contained no reducing substance. Urine passed six hours after injection contained 6 per cent. of sugar by fermentation (6.11 per cent. by Fehling) and yielded a typical glucozazone. No more urine was secreted. The animal died about twelve hours after the injection, after having had bloody diarrhea.

Autopsy.—Peritoneal cavity contained about 30 c.c. of bloody fluid. Entire gastro-enteric tract, from lower end of esophagus to anus, intensely congested. Mucosa deep purple color, surface denuded of epithelium. Congestion most intense in descending colon and rectum. Pancreas unevenly hemorrhagic and congested throughout. Liver and spleen normal. Kidneys slightly congested. Suprarenals appear slightly congested at junction of cortex and medulla. Tissues preserved in Ohlmacher's fluid. Sections through descending colon show mucosa to be entirely denuded of epithelium in places. Submucosa is seat of numerous and extensive hemorrhages. Pancreas shows considerable congestion, most noticeable in the capillaries close to the islands of Langerhans. Many lobules are the seat of hemorrhage and near such hemorrhages the secreting cells are in all stages of disintegration. Numerous focal necroses involving nearly entire lobules. In some parts the acini are well preserved. Between the necrotic areas and the well preserved acini are zones of acini showing various grades of cell degeneration. In places the cells composing the islands of Langerhans show only slight degenerative alterations of the cell-bodies, the nuclei retaining their normal structure and staining properties. In very many places these cells are markedly altered, the protoplasm of the cell-bodies showing a high degree of granular degenerative change. The cell nuclei have in many instances lost their chromatin, and are barely distinguishable. Many of these nuclei are very pale and some show no coloration by hematoxylin. It is noticeable that in many places the acini about these much damaged cells are comparatively well preserved. The acini that are not necrotic are widely separated and the connective tissue is looser than normal, suggesting the presence of edema. The kidney shows only the signs of acute congestion. The suprarenal structures are unaltered.

Experiment II.—Small dog (about 20 lbs.). Animal bled; 30 c.c. for sugar determination. Urine collected at this time reduces Fehling's very slightly. Soon after bleeding received 6 c.c. adrenalin in peritoneal cavity (1-1,000 solution). Urine passed forty-five minutes later contained an abundance of reducing substance (Fehling's); by fermentation 4.20 per cent. glucose. Vomited several times within a few hours of injection; later had bloody diarrhea. Urine passed during

---

*The observations referred to in this paper were made partly in the laboratory of Dr. Herter, partly in the Laboratory of Physiological Chemistry, College of Physicians and Surgeons, Columbia University.

night after injection reduced Fehling's strongly. Urine in bladder twenty-four hours after injection contained 0.4 per cent. glucose. Animal bled for sugar determination, then bled to death.

Autopsy.—Congestion of mucous membrane of stomach, lower jejunum and ileum in patches, intense congestion of greater part of rectum, irregular congestion of colon. Pancreas irregular and finely mottled with pink. Appears normal on section. Kidneys and spleen look normal. Suprarenals look congested in cortex. Blood drawn before injection contained 0.163 per cent. sugar. Blood drawn after injection (when urine contained 0.4 per cent.) contained 0.174 per cent. glucose.

Experiment III.—Large mongrel terrier (about 40 lbs.) received 10 c.c. adrenalin solution (1-1,000) intraperitoneally. Urine drawn within five minutes after injection contained 0.25 per cent. glucose. Urine collected next day did not reduce Fehling's. Animal vomited after injection, but showed no prostration and had no diarrhea. Recovered.

Experiment IV.—Large dog (about 30 lbs.), bled for sugar determination. Urine collected after bleeding free from sugar. Injected intraperitoneally 18 c.c. adrenalin solution (1-1,000) which had been boiled for five minutes. In half an hour animal became violently excited and remained so for more than one hour, howling continually. Vomited several times. Refused food six hours after injection, but drank water. Urine collected four hours after injection contained 3 per cent. sugar by fermentation and reduced Fehling's strongly. Recovered.

Experiment V.—Large dog (about 50 lbs.); urine free from sugar. Received 8 c.c. adrenalin solution (1-1,000) in peritoneum. After remaining quiet about half an hour after injection, vomited and became violently excited for more than one hour. Excitement then gradually wore away. Urine collected four hours after injection contained 9.17 per cent. of glucose and 1.84 per cent. nitrogen. The ratio of nitrogen to dextrose was thus 4.98. Six hours after injection, animal refused meat, but drank water. Day following injection animal appeared in good condition and urine was free from glucose. Recovered.

Experiment VI.—Small dog (about 18 lbs.); urine free from sugar. Received 8 c.c. adrenalin solution (1-1,000) in peritoneal cavity. One hour later urine contained 6.9 per cent. glucose. Eighteen hours after injection urine contained 2.0 per cent. glucose. Forty hours after injection no reducing substance was present in the urine passed at this time. Recovery.

Experiment VII.—Small dog (14 lbs.) received 5 c.c. adrenalin solution (1-1,000) intraperitoneally. Soon vomited. No excitement but some prostration and drowsiness. Urine before injection 0.46 per cent. glucose (Pavy's method); after injection (twenty-one hours later) urine contained 5.26 per cent. glucose.

Experiment VIII.—Large dog (about 40 lbs.). On January 14th given 1 gm. phloridzin under skin. Next day urine, previously free from sugar, contained large quantity of glucose. January 15th received 1 gm. phloridzin under skin. January 16th urine continued to show large quantity of glucose. January 18th urine contained about 1 per cent. glucose. Animal fasted from January 14th to 18th. On evening of January 18th received a moderate allowance of lean meat. Animal then fasted until evening of January 23d. On January 22d, urine being entirely free from reducing substance, the dog was given 10 c.c. adrenalin solution (1-1,000) intraperitoneally. Urine collected four hours after injection failed to reduce Fehling's solution in the slightest degree. Urine passed about twenty hours later reduced Fehling's solution slightly (0.1 per cent. glucose). Soon after last collection animal received 1 gm. phloridzin. Next urine passed contained an abundance of glucose (1.28 per cent. glucose).

Experiment IX.—Dog (24 lbs.) received 7.5 c.c. adrenalin solution (1-1,000) under skin. Urine before injection 0.31 per cent. reducing substance (Pavy); twelve hours after injection 0.47 per cent. reducing substance. After this collection animal received good meal. Eight hours later 10 c.c. adrenalin (1-1,000) in peritoneal cavity. Four hours later urine contained 5 per cent. glucose.

Experiment X.—Dog (30 lbs.) received 10 c.c. adrenalin solution (1-1,000) under skin. Urine before injection 0.48 p er cent. reducing substance (Pavy). First collection after injection 0.66 per cent., second collection 0.52 per cent. reducing substance.

Experiment XI.—Dog (50 lbs.) received 15 c.c. adrenalin solution (1-1,000). Urine before injection contained 0.33 per cent. reducing substance (Pavy); second collection, 0.57 per cent.; third collection, 0.42 per cent.; fourth collection, 0.46 per cent.; fifth collection, 0.44 per cent. reducing substance. Second, third, fourth and fifth collections were made *after* injection.

The observations here recorded show that the intraperitoneal injection of adrenalin solution (1-1,000) in doses varying from 6 to 10 c.c. was in each instance followed by the appearance of glucose in the urine.[5] In one instance the percentage reached 9.17 per cent.; in another it was as low as 0.25 per cent. In one instance the sugar appeared in the urine in less than five minutes. Two of the dogs died. All vomited and showed more or less violent excitement after the injection. Those which recovered showed some degree of prostration twenty-four hours after the injection. With two exceptions the dogs used had been on a diet of lean meat previous to the injections.

Experiment VIII. appears of special interest, because an effort was made greatly to reduce the store of carbohydrate material by means of injections of phloridzin together with deprivation

[5] Since the foregoing was written an observation has been made regarding the local application of adrenalin solution to the pancreas. Dog, previously used in Experiment V., after his recovery and the disappearance of glucose from the urine, was etherized and the abdominal cavity opened. Pancreas exposed and 1 c.c. of adrenalin solution (1-1000) plus 1 c.c. of water applied to its surface by means of a soft brush. After a slight immediate blanching of the gland, congestion followed simultaneously with the appearance of glucose in the urine, ten minutes after application of the adrenalin solution.

of food. It is noticeable that urine collected four hours after the injection did not contain any sugar, although glucose subsequently appeared in very small amount.

Another feature of interest is the fact that an abundant excretion of glucose followed the injection of an adrenalin solution which had been boiled for five minutes. We should expect any diastatic ferment contained in the extract to be destroyed by this treatment. Indeed the method described by Takamine[6] for the preparation of adrenalin renders it most unlikely that any diastatic ferment would resist the injurious action of the heat employed in the course of the process for the purpose of getting rid of albuminoid substances. To accomplish this involves an exposure to 90° to 95° C. for a period of one hour.

It may also be pointed out that adrenalin can be added to a solution of glycogen and kept in the incubator for twenty-four hours without any conversion of glycogen into sugar. These different considerations show that there is no reason for attributing the glycosuria from adrenalin to the presence of a diastatic ferment. There is also no satisfactory ground for referring to a diastatic ferment in the suprarenal body the glycosuria caused by any extract of this gland.

Attention is directed to the observation that the dogs which received adrenalin subcutaneously showed only a slight increase in the reducing substance of the urine. With doses of equal size these results contrast sharply with the glycosuria following intraperitoneal injections.

The alterations noted in the intestine and pancreas in Experiment I. are remarkable. They indicate that the suprarenal extract is capable of inducing changes of a highly destructive character in these parts. How these alterations are brought about we shall not undertake to discuss here, as it is our intention to speak of these lesions more fully in another connection.

While we do not at present care to express an opinion as to the relations between the glycosuria caused by adrenalin and the lesions observed in the pancreas, it may be stated that we have already made observations which suggest that this glycosuria is in reality of pancreatic origin. It is not, however, maintained that advanced pancreatic lesions like those to which we have referred are essential to the glycosuria in question.

Among the topics which we reserve for future discussion in connection with adrenalin glycosuria or diabetes are the glycogen content of the liver and muscles and the sugar content of the blood.

We feel justified in emphasizing the following facts:

1. Adrenalin given intraperitoneally is capable of inducing a marked glycosuria, in which the percentage of sugar may reach 9.17 per cent., and the ratio of nitrogen and dextrose 4.98.

2. Adrenalin glycosuria is not dependent on the presence of a diastatic ferment stored or formed by the suprarenal gland.

3. Adrenalin injections are sometimes followed by destructive lesions of the gastro-enteric tract and pancreas.

4. After a fatal dose of adrenalin the cells composing the islands of Langerhans were found to be the seat of granular degeneration, very pronounced in some places. The nuclei of many of these cells showed extensive loss of chromatin substance. In some parts of the pancreas the cells of the islands of Langerhans were much more injured than the surrounding cells of the secreting acini.

6. With equal doses of adrenalin the intraperitoneal injections proved much more efficient in the production of glycosuria than injections under the skin.

[6] Loc. cit.

SANITARY ASPECTS OF NICARAGUA VS. THOSE OF PANAMA.

BY J. EDWARD STUBBERT, M.D.,
OF NEW YORK;
FORMER CHIEF SURGEON OF THE NICARAGUA CANAL COMPANY.

In the Medical News of January 4th appeared an article entitled "Sanitary Aspects of the Panama and Nicaragua Canals," written by Mr. Soper, of New York, Sanitary Engineer, in the opening paragraph the article is referred to as being a disinterested one. To those familiar with the physical and climatic conditions of the two routes, as well as with their medical history, two facts are to me very patent, viz., either the article referred to is not a disinterested one, or the writer is from my point of view misinformed concerning his subject.

He states the truth when he says, "Not only is the question of health a factor to be considered in the construction of the canal, but when the canal is completed the rôle of this great waterway, in promoting or endangering public health, will be a subject of immense commercial importance;" but it is astonishing for him to say, "Since the period of the Spanish conquest, many attempts have been made to colonize Central America, but the foreigners of Spanish extraction are the only ones who have been able to withstand the climate with even a tolerable degree of success." The truth is that Central America possesses many beautiful spots of great healthfulness and large foreign colonies have lived successfully there for years; and, if the same common sense is observed in selecting sites for residences as is observed in the United States and European countries, the Anglo-Saxon can live at least as many years and with as perfect health in Central America as elsewhere. The description of the physical condition of the natives can be applied justly only to a few of the Peon class, who are located along some of the low, malarial districts. The writer of the article referred to also shows a lack of precise knowledge of geographical as well as political lines by confounding Central America with the Isthmus. Those acquainted with these countries are well aware of the fact that the Isthmus is not within the bounds of Central America, the five republics of which district are all situated north of the Isth-

mus of Panama, which lies within the limits of South America. This misconception of the subject is perhaps not to be wondered at, when many intelligent people in the United States think that Nicaragua is situated south of the Isthmus of Panama. The fact is that between Nicaragua and the Isthmus proper is situated the high and mountainous republic of Costa Rica.

Now, as to the comparative healthfulness of the two districts, in referring to Panama, this writer says, "According to Wallis, 'smallpox, yellow fever and paludal fevers in their infinite varieties and forms are never absent from these intertropical regions where they are truly endemic.' Nelson, after an experience of five years at Panama, gives his approval of the statement long made with reference to the Isthmus, that it is the 'Grave of the European.' It has also been called the 'Pest House of the Tropics,' and Bigelow says that here truly 'Life dies and death lives.'

"In the contracts let by the old Panama Canal Company, the latter was compelled to supply the labor. The total population of Panama was estimated at not above 150,000, and, as many thousand workmen were required for the work upon the canal, it was necessary to import labor from abroad. In the effort to supply the demand, many laborers were brought from the Island of Jamaica, but of these many soon fell sick and died, and a large number of the remainder left the work to escape a similar fate. Other workmen came from Carthagena, the British Antilles and the lower Mississippi Valley. Of all the labor employed, the most hardy workers, as regards ability to endure hardship and resist disease, were a tribe of Indians from the Magdalena River.

"The sickness and loss of life among the men engaged at work upon the canal have been variously stated. Davidson declares that of a force of 7,000 men, the company reckoned that about 1,000 men were always in hospital. From other sources we learn that the sickness and death-rate among the laborers were very high. In Panama and its vicinity 37 engineers out of less than 100 are said to have died during the months of March and April, 1882. An observer declares, 'There was a single French engineer who had been able to attend to the work beyond one year and a half, although the contract called for two.' In September, 1884, it is said the Canal Company buried 654 officers and men. There were many sanitary abuses when the canal work was first begun, and the method of charging the contractors for the care of the men in hospital no doubt caused the laborers to be kept at work when they should have been under medical care.

"The health conditions as officially reported by French authorities, do not show the high mortalities from diseases incident to the climate which have been indicated by travelers and other independent observers. But Heffenger declares that it was impossible for him to gain access to the health records of the Panama Canal Company and that the impression gained by him after investigating the matter privately was, that the public reports were garbled and incorrect. Dr. Heffenger states that he was informed by a leading physician of Panama that in the first eleven months, during which preliminary work in the canal was under way, 65 officers and 800 men died of disease.

"It is recorded by Liddell that 382 patients treated by him between the middle of June and the succeeding May, 250, or more than two-thirds, were suffering from remittent fever with bilious, gastric or enteric complications. Referring to the importation of labor for the Panama Railroad, Liddell says that the services of laboring men from the United States could not be counted on for three successive months. Before the end of the second month one-half of the force was on the sick list or enfeebled by sickness already sustained."

The foregoing statements as to the fatality of the climate along the Panama route, or what is truly the Isthmus, are not at all exaggerated. It has been roughly estimated that, in the construction of the Panama railway, every cross-tie represents a human life. Let us look at the other side of the picture, namely that of the health records of Nicaragua. Carefully kept medical statistics show that *the death-rate among the employees at work along the route was seven-tenths of one per cent.* The greatest amount of sickness was encountered in building a railway through a swamp, eight miles from the coast to the foothills. In constructing this route, laborers were obliged to work all day long in swampy water varying from three to five feet in depth. The laborers were drawn, as in the Panama enterprise, from Jamaica and other West Indian islands, with a small percentage of Anglo-Saxons from other countries. In no instance, as far as my memory goes, did an Anglo-Saxon employee of the Canal Company who was engaged in work along the line die from any climatic disease when the proper rules of living were observed. Nearly every employee, along the Nicaragua route had an attack of malarial fever within a short time after landing, but the hospital record shows that the average length of time that such an attack incapacitated a man for work was five and one-half days, thus proving that this same form of remittent fever is less severe and of shorter duration in Nicaragua than in our own Southern States.

Contrary to the statement of the writer of the article referred to, I wish to say emphatically that cases of pernicious fever were not numerous along the Canal route. Epidemics of pernicious malarial fever do occur in the cities of the interior of Nicaragua in the fall months, but, comparatively speaking, their number is small. During a time when towing steamers were busy between Colon on the Isthmus of Panama and Greytown in Nicaragua, it is a notable fact that some of the crews engaged in this work developed Chagres fever, and *it is remarkably significant that every patient with this disease who*

was landed at the Nicaragua port recovered, while a large percentage of those landed at the Panama port died.

Yellow fever is always present, more or less, on the Isthmus of Panama; never, to my knowledge, has a single case been seen along the line of the proposed Nicaragua Canal. Isolated suspected cases have been met with well to the west of the route, between Managua and Corinto. I have seen many of these cases personally and have always been of the opinion that they were nothing, more or less, but exaggerated cases of pernicious fever of the icteric variety. One important factor would seem to settle this in the minds of disinterested observers, namely, that the victims of this fever had recurring attacks, from fourteen days to a number of months apart, and but very few of them died in the first one. Moreover, the paroxysms were generally absolutely controlled by the hypodermic administration of quinine.

The men engaged in work along the Nicaragua Canal in the jungle or forest, after reaching the foot-hills, showed a very small percentage of illness and no fatality. The lake region in Nicaragua is notoriously healthy, while along the western division, between the lake and Brito, we find a region healthful in every respect for foreign residents.

Greytown, at the eastern terminus of the Nicaragua route, also possesses among its permanent residents, as compared to Colon and Panama, a remarkably good health record. The physical conditions of the two countries make very plain why Nicaragua is more healthful than Panama. One can satisfy one's self on this point by studying the papier-mâché models of the two routes. On the Nicaragua route, at the east end, there is a short distance of five or six miles through swamp land with a sandy bottom, or, in other words, mostly made land from the ocean; from this point, the hills rise with such abruptness as to make rapid currents in the numerous small rivers flowing from them. The broad San Juan River itself is a mighty stream, flowing with great velocity from Lake Nicaragua to the Atlantic seaboard. When we reach the lake, there is an immense body of water across which are blowing, twenty-eight days out of every thirty, the strong northeast trade winds which have come across the Caribbean Sea. These same winds are probably greatly responsible for the healthfulness of Greytown, or the eastern terminus of the Canal.

The writer of the article referred to placed considerable stress upon the excess of rainfall at the eastern terminus of the Nicaragua Canal. I simply have to reply that it is an open question in the minds of observers of experience whether or not excessive rainfall necessarily means greater unhealthfulness. I am inclined to believe the contrary. Even allowing—which is a fair deduction—that during the work of more active construction the mortality along the Nicaragua route would be greater than during the so-called preliminary work, all well-authenticated statistics, derived from actual experience rather than from antiquated records of individuals, should lead us to believe that the death-rate along the Nicaragua Canal can never even approximate that experienced on the Panama route, and that, after the Canal is once built, the country should resume its present healthy conditions and be a safe place for tourists and pleasure-seekers. In fact, there is reason to believe that on the island of Lake Nicaragua there could and would be established a favorite winter resort, fully as attractive and healthy as some of our noted West Indian Meccas for pleasure-seekers. The mountainous regions that surround Lake Nicaragua abound in beautiful and healthy locations among the coffee fincas. No sane man would ever do more than travel over the Panama route as rapidly as possible.

The conclusions which I believe may be drawn from reliable statistics are as follows: (1) The natural conditions of the Central American or Nicaragua route are far more conducive to health than those along the Isthmus of Panama route. (2) The endemic diseases of the Panama route are far more fatal than those along the Nicaragua route. (3) During the time of actual construction, while there would necessarily be an increase of sickness, the mortality would be remarkably below that on the Panama route. (4) After the completion of the Canal, the regions bounding the Nicaragua route would be capable of development by the Anglo-Saxon, while he could not safely live along the Panama line.

Finally, let me draw attention to the fact that much more money was spent *per capita* by the medical department of the Panama Company than by the Nicaragua Company, and yet the results are in favor of the latter Company; and perhaps the most significant of all as weakening the argument of the article referred to, is the fact that the writer acknowledges that he had been unable to obtain authenticated statistics of the French Company, while those of the American or Nicaragua Company have always been open to those who cared to read them. It is a well-founded belief of many students in this country that there is a very patent reason for the withholding of the statistics of the Panama route.

Although the Canal Company has sent in a supplementary report to the Construction Committee in favor of the Panama rather than the Nicaragua route, they have done so on engineering and financial grounds, stating that they still adhere to the opinion that the hygienic conditions are entirely in favor of the Nicaragua route. This opinion has been expressed by men who have personally investigated the matter.

25 East Forty-fifth Street.

German Medical Society.—At the next regular meeting of the German Medical Society, to be held Monday, February 3d, Dr. F. Maass will read a paper on "Operations for Tumors of the Nasal Passages" and Dr. M. Einhorn will report a case of "Hodgkin's Disease and Lymphatic Leucemia."

A WORD ON SPECIALIZATION IN MEDICINE AND SURGERY.[1]

BY WM. M. POLK, M.D.,
OF NEW YORK;
PROFESSOR OF OBSTETRICS AND GYNECOLOGY, MEDICAL DEPARTMENT, CORNELL UNIVERSITY; GYNECOLOGIST TO BELLEVUE HOSPITAL, ETC.

In looking for a subject for this occasion, I selected one which touched the principle upon which your institution was founded and upon which it has rested ever since, viz., the specialization of surgical work.

As the area of surgery broadened and deepended, there were some who felt, as in other fields of human endeavor, that better results could be obtained in this were individuals or groups of individuals to concentrate study upon certain regions of the body, thus attaining better understanding of the causes and behavior of the disorders occurring therein and becoming more skilful in dealing with them. The same question, however, arose that had always met specialization, no matter where applied, namely, Where shall the lines of demarcation be fixed? A student of your history learns that in the contention upon this point you came near defeat, but truth is mighty and will prevail, so you scored victory. The general surgeon, as he is called, was your foe and a strong one as well. Holding the conviction that there was no good surgeon but the one who was equally at home in all parts of the body, he presented precedent and invoked practice to sustain his position; in all of which he was within his rights as then recognized, for his education was, of course, planned to cover the entire body, and it is hardly too much to say that he was generally regarded quite as competent to extract a cataract from the eye as to cut off a leg. But his eye was opened to the advantages of some specialization by what he saw was happening with eyes he left to those of his guild who were giving special attention to their ailments. This in reality established a precedent for further contention for special privileges. To be gained, however, as was but right, the necessity must be proven, then insisted upon, and continuously striven for. From such an effort grew this institution, the first, I believe, in the world, and a striking triumph of the doctrine of woman's rights. I have already cited the familiar adage, "Truth is mighty and will prevail," as the basis of your victory over the forces contending against your recognition. But I really think the woman in the case did more to turn the scales of victory your way than did mere abstract truth. I fear the venture would have long sat outside the gate had not her potent fingers touched springs and unloosed fastenings, leaving but dead weight to those whom Nature has always placed at her disposal.

Since I have said so much, perhaps, in view of the more or less professional character of this audience, it would be better to digress a little and say a word upon the general subject of specialization in our profession, medical as well as surgical, that which touches the general physician as well as that which involves the general surgeon. The problems presented to the physician are of such a nature that a broad view of the subject compels the conclusion that his work can be specialized to but a limited degree, if the interests of the patient are to be subserved. The large majority of conditions he treats are general rather than local, and, of those which are local, most pass of necessity into the hands of the surgeon, and, if not, are apt to form distant connections necessitating radical changes or substitutions of management, such as would carry him far from the initial position, in fact, might and often do carry him all over the field. I venture to say that most, if not all, of you have had experience verifying this statement. It is not sufficient answer to reply that, the function of the specialist being concentration of study upon one or a set of ailments or organs, he therefore is in the best position for early detection of divergences and for speedy application of remedy, because, so complex is the interrelation of organs which can be selected for specialization in medicine, a disease in one may have its first open manifestation in the derangement of another; hence, even should one begin as a specialist, he would be quickly driven to cover the whole field. With perhaps the exception of the specialty of nervous ailments, those which obtain in medicine are really based as much upon the physical and mechanical as upon the mental limitations or requirements of the situation. He who deals with sound and its variations, as with heart and lung ailments, must be clever with his ear, and he who looks after the children must be at all times a general practitioner and yet possess the time and patience to meet all sorts of irregular calls from beings who can tell him little at first hand, except through involuntary and unconscious expressions and attitudes, needing some special adaptation or training on his part properly to interpret. The only real specialty in medicine is neurology, rendered so by the dominant and decisive influence of the nervous system, and the need on the part of the practitioner for great elaboration of method in exploring a case and extraordinary patience and self-control in the management of people in whom will power is often wanting as an aid in cure.

The essence of surgery is a knowledge of topography of the function of the organs and a familiarity with the processes of inflammation and repair. A surgeon must be an anatomist, a pathologist, and a physiologist. He must have profound knowledge of all conditions of the system which influence its reparative work and must know how to differentiate conditions requiring his aid from those which the patient can master without it. But, after all this is acquired, that man is the best surgeon who has at his ready command the most complete acquaintance with the region in which he operates, not only as it is normally, but as it may be altered by disease, so that, entering it, he may never be at a loss how to

[1] Anniversary Discourse, Woman's Hospital, Nov. 21, 1901.

proceed in order to get the best result with the least damage to the structure or organ involved and those adjacent thereto. It is evident, therefore, that the man does best who, having a good education in the principles of surgery and some experience in their general application, brings to his aid the widest experience in the section he is called upon to enter. When we realize how region after region of the body has been brought within the domain of surgery, how, where but yesterday medicine reigned supreme, to-day surgery prevails, insuring cures and saving lives which were abandoned, we see the enormity of the task put upon any one who attempts to cover the entire field. In the interest of surgery, then, some division of the field is wiser, in fact, more essential, than in medicine. It would make my remarks to technical, perhaps pedagogic, were I to attempt demarcation before such an audience, but it is not necessary; it is requisite only to make a general statement of the reason for the principle for which you stand. I must also say that here, as in no other department of human work, care must be taken to avoid extending too far the application of the principle. Its limitations will be fixed by results, for in the long run that specialty will survive and flourish which can show a better all-round result for the patient than can be had in the general field. The interest which all this possesses for you lies, first, in the pregnant fact that this Hospital represents the earliest organized and successful effort to erect gynecology into a distinct surgical specialty, and, second, in the question, How far have results justified your creation and continuance? It is scarcely fair to make you answerable for all the good or evil which has followed your initiation, but your influence has always been so powerful that any question touching gynecology must come home to you, for you have been its chief exponent.

For thirty years your position was all the most sanguine advocate could desire. Your influence was enormous, not only here, but throughout the world; the good you did is incalculable. Manual dexterity by workers who gave themselves to a thorough mastery of all details that pertained to the problems involved was the basis of your success. But there came a change. You were sending broadcast throughout the country men specially versed in your ways. The field of gynecology, practically ignored before, was rich in material and in reward. The temptation to enter it was great, so great that soon the country swarmed with those who, seeing your success and that of your graduates, professed to know your methods, to do your work. These novices would have discredited themselves at once, but for the introduction into surgery about this time of one of its greatest aids, the antiseptic or aseptic method of treating wounds. It seems paradoxical that an evil could spring from so great a good, and yet this is just what happened. This was the manner of it. Acquiring the knowledge that, under the cover of asepsis, wounds might be inflicted with comparatively small risk, these adventurers ignored nearly every other requisite of surgery and boldly entered where wiser men were treading with painstaking circumspection, and, though perhaps they met with success, it was generally of that kind you have heard of so often in which, in spite of it, somehow the patient did not do well. Too often unsatisfactory and ill results remained. So this specialty, so rich in opportunity, became the prey of incompetence, of ignorance, and of qualified quackery, from one end of this country to the other. The reaction in the professional mind which has shown itself is but the natural outcome of the laxity with which the better and what should be the guiding forces in our specialty have viewed and even continue to view the pretenders and their work. General surgery, from motives quite as human as any actuating us, is doing its best to regain the field, to bring it all back within the domain of the general surgeon, and if it can do the work better, it should do it and will do it. But it cannot. That which it will do, however, is this: Educate men in its hospitals in the general principles of surgery and its practice, giving them such opportunities for special work as their material and time will permit, trusting to a fuller acquaintance and the development and perfection of a special operative skill from further opportunities gathered in the walks of subsequent private practice.

Facts are stubborn things and the sooner faced, accepted and acted upon, the quicker the victory. In the face of present surgical perfections, it is truer than ever before that no great and worthy success can be reached in any of the departments of surgery by any one deficient in a thorough knowledge of its principles, and the one who first studies these principles as exemplified in practical surgery in general, and then as exemplified in the region or regions he intends to specialize, will make the best specialist. With such a foundation, the greater the opportunity for special study, the higher the perfection. You, as the foremost exponent of gynecology, must therefore, in common with all like institutions, take all this into serious consideration. Not only is your own life bound up in it, but the welfare of the specialty itself, for, if it can be shown that the general surgical hospital is able to turn out as good specialists as you can, in time you will wither and die. But mend your methods and you will prevail and that speedily. Recognize that you cannot from the very nature of your restrictions give the broadest surgical training, that this can only be had in a general surgical ward, and require therefore that every one who holds a place upon your resident staff shall have had such training. But, as Art is long and time pressing, consider that one coming with such preliminary training does not need to give the time you now exact to acquire that degree of special training required for good work outside your walls. Shorten your term of service so as to tempt men already provided with the two years required in the general hospital to continue their studies with you, who, for the present at

least, can still show them every variety of the special ailments they seek to master. In this way you attract the best of those who desire to specialize in your direction; you set your seal upon them and turn them forth to battle successfully for your fair name and for that of the great specialty you represent.

The tendency of all specialization is to narrowness and to exaggeration of minutiæ. The safeguard is a broad foundation, a thorough knowledge of the principles governing the whole field, and a practical acquaintance with their expression as witnessed in disease, and their application as required in remedial measures. Let the specialist be rather like the carrier-pigeon, which, when set free, circles round and round, ever rising higher and higher as it studies the general field, till, finally, gaining its elevation, it singles from the horizon the special direction it will take, and then flies straight as the arrow from the bolt to the place where it would be.

The curse of our profession to-day is the half-baked, underdone specialist, and this country is full of them. By their exaggeration of detail and magnifying of minutiæ, they blind the credulous, prey upon the nervous and the apprehensive, and end in disappointing the patient and bringing discredit to the profession they claim to adorn. Their work has done more to stimulate the medical fads of the day, Christian Science and all kindred things, than all else put together. The weary sufferer, heart-sick from a hope that could but be deferred, inasmuch as it is often based on the ignorant assumptions of an adviser who claims, and in too many instances has, reputable professional connections, abandons himself to any cure which irregular quackery may suggest.

And now, in the evolution of this discourse, I have reached a point at which I can cease to speak from the standpoint of the doctor and address you from that of the patient; for, after all is said that can be said upon the subject of proper medical and surgical training, the patient is the principal objective. It is for him and for her that the doctor exists and in making one or many of them trustworthy and efficient, it cannot be at the expense of the welfare of your charges. Trustworthy and efficient—and what constitutes trustworthiness and efficiency in one whose life is given to the alleviation of human sufferings? Can he view this body as but a laboratory of chemical action and reaction in which only physical forces are concerned, to which his mission therefore is merely that of one who adds this or extracts that, as these forces rise or fall in life's struggles? Can he see in it but a stick or a stone to be hewed or chiseled as lacking symmetry may suggest, or does he see that the essence of the being stricken before him, the mystery in it, that calls itself "I," is a breath of Heaven; that "that body, those faculties, that lie before him, is it not all a vesture for that unnamed"? Yes! a thousand times, yes! Trustworthiness and efficiency in our calling mean this and more. For in consecration of the work, as a light to make radiant every step of this arduous and self-sacrificing calling, he who is efficient and worthy of trust must see, can only see, that there is but one Temple on earth, and that is the body of man, built by God and with man's consent placed in our hands for safe-keeping. Mercy, gentleness, and skill will always go hand in hand with those who, accepting the charge, see who is the real dweller in that Temple, the breath that is the breath of Heaven, and such men, fitted for life's struggles as you are so well able to fit them, will never do other than ennoble all they touch.

MEDICAL PROGRESS.

PEDIATRICS.

Infantile Hepatic Cirrhosis with Ascites.—A case of hepatic cirrhosis of biliary origin occurring in a child of eight years is reported by Variot and Roy (Gaz. hebd. de Méd. et de Chir., Dec. 19, 1901). The history presented neither alcoholism, malaria nor other morbid antecedent. The child when first seen had marked ascites, well-developed collateral circulation, a large, smooth liver extending beyond the free border of the ribs; there was no icterus, no splenic hypertrophy. The possibility of a tuberculous hepato-peritonitis was considered and tuberculin was injected to the extent of 5 milligrams, but the elevation of temperature which resulted was less than five-tenths of a degree. Absolute milk diet was ordered, but the abdomen continued to swell, passing from 60 to 81 centimeters in circumference. Paracentesis was practised, and in succession five, six, then seven liters of clear serous fluid were withdrawn, containing chiefly epithelial cells with a very few lymphocytes. Shortly after an exploratory laparotomy the child died. The liver presented biliary cirrhosis. The extrahepatic ducts were manifestly diseased and the gall-bladder was thickened and contracted. The microscopical findings confirmed the diagnosis of a cirrhosis of biliary origin. Of clinical interest are the absence of icterus, the lack of enlargement of the spleen, and the absence of any notable enlargement of the liver itself.

Etiology and Morbid Anatomy of Tuberculous Meningitis.—A series of 27 cases of tuberculous meningitis personally observed during life and subsequently examined in the dead-house furnishes the material for a paper by E. Cautley (The Lancet, Dec. 21, 1901). No less than 22 of the 27 cases occurred during the first five years of life and only 5 during the second five years. In only one case was it stated that the mother was affected; in 22 cases it was definitely declared that there was no history of tuberculosis in the parents or in other children; in 4 cases the possibility of direct infection from a parent was present. In one instance only could injury be invoked as an etiological factor. In discussing possible channels of infection Cautley points out that in only two instances were the mediastinal glands normal; in these instances the tuberculous process was limited to the base of the brain. In 23 cases the mediastinal glands were caseous; the gland situated at the bifurcation of the trachea was most often affected. In 9 instances there was recent disease of the lungs, and in 12 cases extensive tuberculous disease of old standing. In only 2 out of the 12 cases of long-existing pulmonary disease was there evidence of infection of the mesenteric glands; from this fact the author's deduction is that the alimentary tract is not markedly susceptible

to infection by the human tubercle bacillus. Cautley does not take a very optimistic view of the prospect of operative treatment proving beneficial. In one-third of his cases there was no excess of fluid in the ventricles; in the remainder the fluid varied from a slight excess to a large amount. In many instances the cerebral tissues were soft and almost diffluent. Operative treatment can be indicated only under the assumption that the child is dying from coma induced by pressure. But many children died comatose in whom after death there was no evidence of increased intracranial pressure. Operative treatment would relieve pressure in only one-third of the cases, and even in these cases it would do little or no good on account of the softening so often present, which is dependent upon insufficient blood supply rather than on an excess of fluid.

Exophthalmic Goiter in a Child.—At a recent meeting in Paris, Leroy and Variot (Le Progrès Médical, Dec. 14, 1901) presented a child of four years, who six months previously had developed goiter, exophthalmos and tachycardia. For eighteen months he had had convulsions, and since the onset the symptoms had been much aggravated by an attack of whooping-cough. Strophanthus, bromides and salicylate were given with no result, and the child's condition was deplorable, when it was put on thyroid extract, one pill of gm. 0.1 (gr. ij) a day. From this time there was steady improvement in the condition. The authors also reported cases in which thyroid had done great harm.

Stone in the Bladder in Children.—Changes in the urine produce stones independently of the patient's age. M. F. Porter (Annals of Surgery, Dec., 1901) reports a case of one in a female child four years old. The attacks were for a time considered of intestinal origin and later, after careful inquiry and observation, of renal origin. Soon after this stones were passed with the urine. The trouble began when the baby was only six months old; during the next two years she had a great deal of trouble of the same kind and passed in all perhaps a teaspoonful of stones, ranging in size from that of a millet-seed to that of a large grain of wheat. The attacks ceased and for a while she seemed to be without trouble. When about four years old the patient was seen again and it was learned that for some days while passing urine she had had attacks of pain in a way to suggest stone in the bladder. Under sounding the diagnosis was confirmed. The operation was done two days afterward and the stone removed by suprapubic cystotomy. The stone weighed when thoroughly dry sixty grains and measured seven-eighths of an inch in width and three-eighths of an inch in thickness. The bladder was immediately sutured with catgut and the external wound with silkwormgut and a small wick of gauze left in the lower angle of the wound. This was removed in forty-eight hours. The bladder was drained for five days with the retention catheter and the child was discharged from the hospital on the 12th day of April cured. At the time of operation she was three years ten months and twenty-five days old.

GENITO-URINARY AND SKIN.

Peculiar Bladder Condition.—The case of a man who never had had syphilis but had had chancroids several times and gonorrheal urethritis many years before, and was an alcoholic, is reported by D. P. Anderson (Montreal Med. Jour., Dec., 1901). He says that a black fluid was removed from the right side of the scrotum after it had been there for nineteen years. Physical examination is negative except for double inguinal hernia and enlarged prostate. There is no urethral stricture. Immediately after voiding urine, about two ounces of residual urine can be obtained by catheter. From six days to a month apart, this man has paroxysms coming on during the night, in which he has a desire to urinate and at the same time has a kind of dizziness, fluttering heart, and irregular, intermittent pulse. During the next three hours or so he is obliged to urinate frequently, passing altogether one-half to three-quarters of a vesselful of urine, which is like water and free from albumin or sugar. The irregular heart action lasts about twelve hours longer, when all symptoms disappear, leaving him as well as before. Sometimes defecation is as persistent as urination. The author ascribes this polyuria and tachycardia to a reflex from the bladder brought on by the enlarged prostate.

A New Remedy for Gonorrhea.—Of the two principal classes of drugs which have been used in the treatment of this disease, silver and its preparations have the objection of being irritating and painful, while the various astringent compounds are comparatively inefficient on account of their lack of bactericidal power. A remedy which combines the desiderata of both classes without their unfavorable adjuncts is submitted after clinical trials by E. Jacobi (Deut. med. Woch., Dec. 26, 1901). The preparation has also been used in the treatment of leg ulcers, from which procedure it receives the proprietary name of "crurin." Chemically it is chinolinbismuthrhodanat with the formula $(C_9H_7N.HSCN)_2Bi(SCN)_3$. There are found in the saliva certain substances, combinations of "rhodan," which have a marked antiseptic character and contribute largely to autodisinfection. The astringent properties of bismuth are also well known and it is upon the combination of these effects that the value of the remedy rests. The preparation of the injection fluid is as follows: One gram of the substance is rubbed up with glycerin and water, five grams of each, and then dissolved in 189 grams of water, the mixture being thoroughly shaken. In recent cases two or three daily injections of from three to five minutes each are usually sufficient to cause a disappearance of secretion and gonococci in from ten to twenty days without pain or irritation. If recovery be tardy a supplemental protargol injection may be used once daily. In chronic cases irrigations may also be added, although good results were obtained without them. It seemed best to continue the injections t.i.d. for from eight to ten days after all traces of a morning drop had disappeared and then diminish them gradually. In gonorrhea of the female 10-per-cent. suppositories, in urethra or cervix, have been found of value.

External and Internal Urethrotomy.—The general treatment of urinary extravasations according to a procedure which has not yet found its place in the textbooks is described by Reginald Harrison (Edinburgh Med. Jour., Jan., 1902) in an article on the combined operations of external and internal urethrotomy. The first indication is to provide for the free escape of the extravasated urine by liberal skin incisions. The natural fistulæ do not suffice, however, to drain the bladder and the urethra must be made patent. The best method of drainage is by the perineal route, but in order to make it possible to perform the external urethrotomy upon a grooved staff of ample dimensions, the author first performs an internal urethrotomy of the stricture with the instrument of Maisonneuve. One cannot, however, remain content with the internal section, since it has been found to give rise to urinary fevers and to rigors, unless the perineal section be added to it. Drainage should be practised with a tube which tightly fits the perineal wound and admits of no leakage.

Operations upon the Prostate.—The results following operations for hypertrophied prostates have been

of doubtful utility until recently, and the dangers surrounding operations upon old men—the usual victims of this trouble—have been so great that many able surgeons are wont to advise "cleanly and judicious catheterism." H. LILIENTHAL (Med. Rec., Jan. 18, 1902) reports seven cases in which suprapubic enucleation has been performed; five patients recovered, one died and one received no benefit. He lays especial stress upon the value of making a suprapubic opening, even if perineal section be subsequently necessary. It is the only way in which one can gain absolute certainty as to the condition of the bladder; direct palpation and vision may then be used. Small nodules and masses may be quickly enucleated by this route and, if perineal section be necessary, important and valuable assistance can be given by a finger in the bladder. A complicating cystitis is also thus much better handled. Time is an important element usually in these cases, and the entire operation of suprapubic cystotomy and enucleation may be done in fifteen or twenty minutes. Free purgation and diuresis are important preparatory measures.

NEUROLOGY AND PSYCHIATRY.

Facial Hemiatrophy.—The report of a case of this rare disease in a woman of about twenty-four years, without hereditary taint, is made by L. F. FRANK (Med. Rec., Jan. 4, 1901). It first appeared in the forehead five years ago in the form of pigmented spots accompanied at first by pruritus, tingling and burning, and later by an atrophy of the affected parts. The left nostril, palate and tongue have become involved and recently the left auricle has become smaller and thinner than the right. Only one hundred cases have been reported and all authorities agree upon three etiological factors, namely, (1) the beginning in youth; (2) the predominance of the female sex, and (3) the great frequency with which the left side is affected.

Treatment of Tabes.—Fraenkel's movements have certainly resulted in marked improvement in many cases and, although the general course of the disease is probably not affected, several patients who had been bedridden for years were able to walk with the assistance of a cane after persistent attention to this method. E. BRAMWELL (Indian Med. Rec., Dec. 4, 1901) says that the patient should first be made to understand that his inability to walk is not due to muscular weakness, but to the inability to associate movements correctly; that the treatment is really a process of re-education and that it is not the muscular force which he uses that is of importance, but the care and precision with which he makes the movements. While lying in bed he should slowly raise his foot and touch with his toe an object held a foot or two above. The leg and thigh may then be flexed and after extension of the leg the same object may be similarly touched. These movements should be repeated again and again, constant improvement being sought for. When able to rise he should first be supported and simple deliberate movements tried. More and more weight is put upon the legs and the power of equilibrium trained. Walking along stripes, at first broad, then gradually narrowed and later marked off at intervals of one foot, may be suggested as a valuable exercise. A great number of exercises have been devised for the upper limbs, but these may be easily thought out for the individual case, always making them sufficiently simple in order that the patient may not become discouraged and that he may be impressed with the necessity of being accurate in his movements at the expense of speed and force.

Disseminated Sclerosis.—A case occurring with acute onset in a girl of eighteen years is recorded by J. MAGEE FINNEY (Dublin Jour. of the Med. Sci., Jan. 1, 1902). Within a month there were complete paralysis of legs and arms, loss of control of bladder and rectum, and bedsores on nates and over sacrum. After four months some of the power gradually returned, and she is now able to stand, and to walk some steps with but little assistance. The gait is spastic; knee, ankle, wrist and elbow reflexes are extremely exaggerated; Babinski's sign is marked in the right foot; tactile, thermal and algesic sensation is unimpaired. Coarse and irregular tremors affect the head and upper extremities when the smallest effort is made. Sometimes they are so marked that a glass of water cannot be carried to the mouth. The speech is slow, scanning, with some slurring of the words. The eye examination was made by H. Swanzy, who noted nystagmus, contracted field of vision, and atrophy of the outer portion of each optic disk. There was no retinitis, optic neuritis, or swelling of the disk. The patient has a complaisant cheerfulness, so characteristic in some of these cases, but no other evidence of mental weakness. The organic nervous diseases which may resemble disseminated sclerosis are as follows: Paralysis agitans, general paralysis, mercurial tremors, syphilitic disease of irregular distribution, ataxic paraplegia, intracranial tremors, and transverse myelitis. In a young woman whose manner and personal appearance suggest an emotional temperament, the suspicion of hysteria is sure to arise. The characteristic points in this case are optic atrophy without neuritis and with a disproportionate defect of the field of vision, nystagmus, syllabic speech, intentional tremor, exaggerated reflexes, spastic paraplegia and vesical paresis.

Hemiplegia.—Partial paralysis of sudden onset is not always fatal and hence treatment becomes a very important matter. J. TAYLOR (Lancet, Dec. 28, 1901), after discussing hemiplegia in adults, devotes his attention to it as it occurs in children, a matter often omitted by authors. He says there are two kinds. The first form is that of birth palsy, hemiplegic in type, usually bilateral in distribution, but occasionally unilateral. Its onset regularly occurs during birth, usually in first-born children and in cases in which the labor is long and difficult, or instrumental. The cause is meningeal hemorrhage; the affection must therefore be bilateral because the hemorrhage usually exists on both sides of the vertex. Occasionally, however, it is confined to one side only, and in this event causes true hemiplegia. The other form of hemiplegia in childhood, the ordinary so-called infantile hemiplegia, occurs in the early years of life and usually commences with a bilateral fit or a series of convulsions. The cause of this is uncertain. According to some it is an inflammation in the grey matter; according to others, a thrombosis in the arteries or in the veins. Sometimes there is athetosis and the patient is often subject to fits beginning on the paralyzed side. Another point is also of interest, *viz.*, the frequent maldevelopment of the paralyzed side, which becomes smaller in every way than the opposite side. The treatment of hemiplegia is divided into that of the onset and that of the results of the lesion. During the onset, if possible, the cause of the paralysis must be determined. If it is embolism, complete rest, light food, and extreme care to avoid any strain on the heart are the essentials. If it is hemorrhage, free purgation, light, easily-digested food, leeches to the temples if there is pain, and absolute rest are the main things. If it is thrombosis in advanced life, gentle catharsis together with cardiac stimulants and fluid diet are the best. If it is thrombosis in the young, then mercury and the iodide of potash must be energetically administered. Tumor and abscesses of the brain require appropriate surgical treatment, except that tumor may often be reached by active antisyphilitic remedies. The

results of hemiplegia require care as to the general condition of the patient. Loss of power and rigidity of the muscles call for massage and electricity. In all cases fresh air, gentle exercise and light, easily digested food are required.

Glycosuria and Insanity.—A tangible effort is being made to connect diseases and conditions which show changes in the nutrition of the body with insanity as being in the nature of cause and effect. W. R. DAWSON (Med. Press & Circ., Jan. 1, 1902) reports five cases in which such a connection appears to be more or less distinct. His conclusion is, taking all the cases together, their predominant characteristic was mental discomfort varying in degree and kind. The blood-pressure was high whenever taken during an acute stage of excitement. This association of glycosuria with melancholia was also found by Dr. Leeper, who recently published three cases and by Raimann and others also. The connection between the two therefore seems to be essential in cases of true diabetic insanity. The form of melancholia is that characteristic of cerebral anemia. If this is taken in conjunction with the atrophy found in diabetic brains, as a secondary morbid change, it becomes clear that the mental symptoms are due to cerebral malnutrition in whatever way this may be caused. It follows also from this that persistent glycosuria or glycemia, even if of secondary origin, is not unlikely to act injuriously on the nervous centers. He agrees with Raimann that the origin of the sugar in this second class of cases is in the digestive system and due to a deficiency in the capacity to assimilate sugar. Such a deficiency he has found to exist in a high degree in melancholia, although always present in acute confusion and other forms of insanity. It is merely a part of the general disorder of metabolism in the insane. Glycosuria is not necessarily a sign of bad prognosis in insanity. Of the author's case seven patients five made good recoveries and a sixth promises to get well.

Epilepsy; Definition, Symptoms, Prognosis and Treatment.—"Epilepsy is a disease of which we know extremely little definitely and with certainty nothing at all. Up to a certain point it is agreed as to what cases are to be included under the term; there is much real and trustworthy knowledge as to the etiology of the disease, but its pathology is largely conjectural and its treatment mainly empirical." In these admirable words W. H. BROADBENT (Brit. Med. Jour., Jan. 4, 1902) paints a clear word-picture of this too-little-known disorder. One cannot read the definition without feeling a glow of hope that some day the veil will be lifted. Many epileptics pass through life without the disease being recognized. This may occur in the more-or-less frequent nocturnal form of the lesion—an important deduction can be made from the fact that the atack almost invariably occurs during the minimum cardiovascular activity. It is extremely rare that the seizures take place during mental or physical exertion or excitement. This has a practical as well as a theoretical bearing, for it is not necessary to forbid epileptics to take exercise or to ride, or even to cycle in moderation. What can be the cause of the convulsions which are an invariable accompaniment of the disease? What is a convulsion? It might be called the result of an excessive and disorderly liberation of nerve energy. The precise nature of this force is not known, but it can only be a transformation of forms of energy which are more or less understood, and everything points to a chemical change in the nature of oxidation as its source. In any event, from whatever point of view the evolution of nerve energy is considered, the conclusion suggested is that in the grey matter there is accumulated a substance of an explosive character ready to liberate energy not by gradual combustion, as of coal, but by a sudden readjustment of chemical affinities, as of nitroglycerin. The prognosis turns mainly on whether the case is one due to hereditary inherent tendency or to causes extraneurotic. It is absolutely hopeless if with the liability to recurrent attacks of convulsions there are other evidences of a low type of nervous organization such as moral or mental depravity, microcephalism, or, indeed, any faulty construction of the cranium. Again, it is bad if the fits have begun in childhood or at or soon after puberty. If, however, the patient has mental and physical vigor; if some serious exciting cause has preceded each attack, if the fits have not begun until late, it may be presumed that the tendency to epilepsy is not strong and that it may possibly be held in abeyance. More important than either of the preceding is the condition of the circulation. A low tension is characteristic of the disease. If it has a relatively high tension for the age of the patient there is good ground for hope of recovery. The treatment is chiefly dietetic and hygienic. Should an epileptic boy or girl go to school? Almost always, if the fits are not too frequent and particularly in the case of boys, whose sensibilities are not so keen as those of girls. Bromides must not be given as mere routine, and if the intervals are six weeks or more the administration should be intermittent. The cases in which there is cardiovascular instability offer the greatest opportunity for brilliant results. At night they should be fed hot beef-tea with cayenne pepper or milk to which spirits of ammonia have been added. Epilepsy will repay further study. Jacksonian has been differentiated from true epilepsy; further distinctions will be established, so that in the future one will speak of "the epilepsies" rather than of epilepsy.

OBSTETRICS AND GYNECOLOGY.

Treatment of Adnexial Inflammations.—The conservative treatment of inflammations of the adnexa is thus summarized by R. PICHEVIN (Jour. d. Méd. d. Paris, Dec. 22, 1901): In acute inflammations, (1) rest in bed; (2) vaginal irrigation under low pressure, with hot antiseptic solutions, care being exercised that the return of the fluid is assured; (3) relief of pain by hypodermics of morphine, opium, suppositories, or injections of a solution containing laudanum; (4) limitation of inflammation by ice-bladder applied to the lower part of the abdomen; (5) wet cupping and leeches at the level of the iliac fossa are sometimes helpful; (6) quinine sulphate for fever; (7) purgatives, laxatives or enemata for constipation; (8) milk diet; (9) support of general strength, alcohol being used for depression. In the majority of cases this line of treatment suffices to abort more serious trouble, or at least to tide the patient over to a safer time for operation, should this become necessary. In subacute and chronic cases, much may be done to relieve and, in many instances, cure if the patient is in a position to give time to the treatment. In such cases the treatment is thus outlined: (1) Prolonged horizontal decubitus is contraindicated as producing venous stasis. (2) Coitus should be prohibited as tending to increase congestion. (3) Revulsion, by iodine, thermocautery or vesicant, is serviceable. (4) Glycerin, pure or combined with antiseptics, such as iodoform or salol, introduced in the vagina through saturation of cotton or sterilized lamp-wick, produces depletion by osmosis of serum, thus assisting in resolution of inflammations.

(5) "Colomnization," much used by Lyons physicians, has yielded good results. By this method the organs are supported by packing the vagina firmly with strips of aseptic or antiseptic gauze or sterilized lamp-wick, saturated usually with glycerin. The packing should be left *in situ* for two or three days, when it should be removed, an antiseptic douche given, and the packing replaced. This treatment should be employed for a long period, with occasional intermissions of two weeks, during which vaginal irrigation should be practised. (6) The effect of this method is enhanced by enveloping the lower part of the abdomen in cotton, over which is applied a rubber bandage in such a manner that it shall exert slight compression. This, with the vaginal packing, tends to immobilize the organs and assists the aqueous depletion through the glycerin, by slight external sweating. (7) Hot vaginal irrigation, the patient being in the recumbent position, is valuable; the same is true of high rectal enemata administered after evacuation of the rectum. (8) Other measures include electricity, uterine massage, and hydrotherapy.

Delivery in Hypermegaly.—A method used in the delivery of an unusually large fetus in which the shoulders became impacted in the pelvis after birth of the head is described by D. J. LARRU (Rev. d. Med. y Cir. Pract., Dec. 21 and 28, 1901). The patient was a woman of normal development and measurements who had previously given birth to children of remarkably large size. Labor pains were severe and the head rotated and descended slowly, but was expelled naturally; after the birth of the head, however, pains ceased and despite all efforts to stimulate uterine contractions there was complete inertia and it was found necessary to interfere. An attempt was made to draw down the anterior shoulder by hooking the finger into the axilla, but without success; the same maneuver failed with the posterior shoulder. The following method was used with satisfactory result: The index and middle fingers were introduced through the posterior commissure, the posterior shoulder pushed well up, fingers withdrawn, and head depressed strongly to the mother's anus, pressure being exerted upon the occipital insertion of the trapezius and mastoideus, with the result that the anterior shoulder glided easily under the pubic arch, the bisacromial diameter being diagonal to the vulva, and after half of the anterior shoulder was born the posterior followed and the rest of the body was delivered without trouble. The child measured 25 cm. from shoulder to shoulder and was 60 cm. in length.

Prolapse of the Cord.—This condition is a great misfortune and unless discovered early and treated successfully is apt to be fatal to the child. Any new method therefore of replacing and retaining the prolapsed cord is valuable. H. HENNE (C'blatt. f. Gynäk., 1901, No. 51) treated a case with ease and success in the following manner: After all other well-known means had failed the cause of such failure was found to be the attachment of the placenta, which was very low down and caused the head of the child to remain in the right aspect of the canal. The method he followed was suggested by the retention of loops of intestine away from the operative field in abdominal sections by means of gauze pads. He took a clean towel, soaked it in a one-per-cent. solution of lysol and squeezed it dry. He folded this into a pad, passed it into the vagina and then, after replacing the cord, gently forced the towel up into the uterus in such a position that the cord rested upon it and was retained by it. The procedure was easily carried out with the help of profound narcosis. The head of the child, of course, had to be pushed upward into the uterus. The intra-uterine hand of the operator was maintained within the canal until pains again appeared. It then guided the head of the child into its proper position and rendered the action of the towel more satisfactory. In this case the remainder of the delivery was normal and entirely free from a recurrence of the prolapse.

EYE, EAR, NOSE, AND THROAT.

Chronic Nasal Disease.—Although the inferior turbinate bone has usually been assigned as the basis for most chronic nasal diseases, it has often been noted that many cases exist which must be entirely out of its influence. C. H. BAKER (Phila. Med. Jour., Dec. 28, 1901) calls attention to the fact that the middle turbinated body has a much greater influence on the course and progress of these diseases, mainly on account of its intimate anatomical relations with the meati and accessory sinuses of the nose, the olfactory nerve and the most sensitive portions of the septum. The meati are readily obstructed by acute inflammations which soon become chronic, resulting in formation of granulation tissue and, later, polypoid growths. The author recommends removal of the middle turbinate in addition to taking out the polyps, as the latter are often thus concealed. Other indications for this procedure are: (1) Sinus occlusion by swollen mucosa which does not respond to cleansing and disinfection; (2) fetid crusting of discharges in the upper portion of the nasal chambers; (3) "bullous hypertrophy" of the bone; (4) nervous disturbances (severe sneezing, nasal asthma, hydrorrhea, headache, tinnitus) due to contact of bone with the most sensitive part of the nasal mucosa; (5) vasomotor rhinitis, as an adjuvant in obstinate cases. His operation is briefly as follows: After a thorough cleansing, an 8-per-cent. solution of cocaine is applied, followed by suprarenal extract. By means of Holmes' middle turbinate scissors the attachment of the bone to the lateral wall is divided from before backward. The cavity is packed with iodoform gauze which is removed on the following day. Frequent cleansing with borax solution is done until healing is complete; the latter may often be hastened by insufflation, the author recommending "dermatine," a lead iodide compound.

Tinnitus Aurium.—So serious may this symptom of disease become that it may lead to suicide or insanity. S. M. YUTZY (The Phys. and Surg., November, 1901) divides tinnitus into the vascular and the membranous forms. The former is due to overfilled or underfilled blood-vessels causing a disturbance of pressure-equilibrium of the labyrinthine fluid. The tinnitus of quinine, salicylic acid, etc., is due to a lowered blood-pressure, as is also the tinnitus of anemia. In membranous tinnitus the tympanic membrane is drawn inward; this is due to inflammatory affections of various kinds or to closure of the Eustachian tube. A valuable point in differentiating the vascular from the membranous tinnitus is that persons afflicted with the latter form hear conversation better when noises are about them, as in a railroad train. This is due to the fact that the numerous sound waves act on the membrane and steady it. Noises have no effect in controlling the flow of blood through the vessels, and hence the hearing is usually made worse by the presence of noises in cases of vascular tinnitus. If more attention be paid to the cause of these affections the treatment will be more satisfactory and more beneficial.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

LEA BROTHERS & CO.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

SATURDAY, FEBRUARY 1, 1902.

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

THE ninety-sixth annual meeting of the Medical Society of the State of New York has had its usual crowded sessions. There could be no better index of the thorough-going desire for professional relations scientific and social on the part of the medical men of New York State and no surer sign of their interest in progressive medicine than the faithful attendance at these meetings. From the beginning of the first until the end of the last session readers of papers were greeted by large and attentive audiences.

This was the best attended meeting in several years. The program of the session was an extremely interesting one and notable even for the State Society. That the organization is able to hold two such meetings as the semi-annual session in New York City in October and the present one, only four months later, is a good sign of vigor of society life and of enthusiastic interest on the part of its members.

The features of the scientific program were the symposia on paresis and on diseases of the pancreas. It is agreed that, while paresis is not so frequent in this country as in the older countries, the disease is certainly on the increase among us. This increase is not of an immediately alarming character, but it calls for the most serious attention as to the possible prophylaxis of the dread disease. There is practical agreement among the authorities who read papers on the subject that syphilis is the main cause of the disease. Other conditions may contribute to the etiology. Overwork and mental anxiety are undoubtedly contributing factors. Excesses of every kind play a rôle, though alcoholism is blamed much less in the matter than formerly. Syphilis is, however, the manifestly determinative agent that produces paretic pathological changes. No profession or trade is exempt from the disease and in America, at least, the proportion of professional men and brain-workers is not higher than that of tradesmen of all classes, from the wholesale merchant to the country baker.

The obscure subject of diseases of the pancreas is being gradually brought into the light and the present review of it will do much to illuminate practical details in the application of recent scientific observations. In addition to these symposia a notable contribution was that of Dr. Noble of Philadelphia on the treatment of pelvic suppuration. His paper brings out the fact that conservatism is the watchword in present-day gynecology. It illustrates a phase of medical and surgical advance that is not so encouraging, however, since it shows that the accepted methods of treatment for pelvic suppuration of the present time are much nearer the methods of a quarter of century ago than they are to most of the intermediate steps by which the conclusion has been reached. Verily the pendulum swings to and fro in human progress and the inevitability of reversion to opinions once thought gone forever, but that contained a precious germ of truth never to be lost, is illustrated nowhere more forcibly than in medical advance.

ROYAL INTERMARRIAGE AND HEALTH.

NOTWITHSTANDING the persistent rumors of the ill health of King Edward VII. some time ago, there have been but faint-hearted denials of the reports that he was ailing, and these have concerned themselves chiefly in regard to his throat. It is said that official action in the matter would only give body to the rumors and arouse sensational conjecture. There are no grounds for thinking that the King is affected by laryngeal cancer, in spite of the very circumstantial reports on the subject in the sensational press, but there seems good reason to think that for a

time there was some pathological condition that disturbed the new monarch not a little.

Writing from London at the beginning of last month Mr. Justin McCarthy, the London correspondent of *The Independent* said: "It is quite certain that the King has been suffering from physical troubles of some kind, though I cannot hear that there is any trustworthy evidence for the apprehensions which are so commonly and so positively made public." Mr. McCarthy hints further that the basis for some of the rumors seems to be that the King has become persuaded that he is not destined to live to the time appointed for his coronation. This phase of the popular report finds some sanction in the fact that the King has lost within a comparatively short time a brother, the Duke of Saxe-Coburg, and a sister, the dowager Empress of Germany, from the dread disease, cancer, to fear of which persistent rumor now attributes his own depression of spirits.

Some of the radical English and Irish papers have recently suggested that at least the predisposing cause of the illnesses which are so common in the royal families of Europe at the present time is their utter disregard of the great law of Nature that discountenances the marriages of near relations. Ordinarily such remarks might be passed over with the reflection that political bias easily led to the assumption of general truths from particular instances. Mr. McCarthy, whose intimate acquaintance with contemporary history is well known by the many readers of his "History of Our Own Times," lends the weight of his authority to these declarations. He says: "At the present time there is hardly a European imperial or royal family which is not oppressed by serious and boding illness of some kind and it is only reasonable to say that some explanation of this fact may be found in the system of intermarriage."

To Americans generally it will, we think, come as a distinct surprise to learn on Mr. McCarthy's authority that with the exception of the King of Sweden, a descendant of Bernadotte whom Napoleon raised from the ranks and later made King, there is not a single important ruler in Europe who is not descended from Mary, Queen of Scots. In Macbeth, which was evidently written with the idea of courting the favor of James I., the first Stuart ruler of England, Shakespeare puts into the mouth of the witches this prophecy to Banquo from whom the Stuarts are by legend descended: "Your children shall be kings." Even the most obsequious of courtiers could not have anticipated how literally true this compliment to the Stuarts through King James was to prove. It is certainly a curious historical fact that the dynasty of the Stuarts, "in many ways the worst dynasty," as McCarthy says, "that ever ruled over England," should have left so many descendants among the reigning houses of Europe.

Meantime there is for the student of medical anthropology the spectacle of a series of inbreeding intermarriages that demonstrates the dangers and effects of marital consanguinity. Perhaps the lesson of the necessity for exercising more care as regards the relationship and other qualities of marital partners may thus be taught by example, if it cannot be enforced by the legal measures that are now so commonly suggested. In a word, the history of the present reigning families of Europe is an open book in which he who runs may read the evils of marriage where new blood is not constantly introduced to modify the degenerative tendencies of the original stock. The lesson may be learned better from a "horrible example" than from the cold logic of statistics on the subject.

A RECENT REPORT FROM THE CRAIG COLONY.

The eighth annual report of the Craig Colony for Epileptics has just been issued and the report of the Medical Superintendent, Dr. W. P. Spratling, contains matter of practical value to those interested in making public provision for this class.

Prior to the establishment of the Craig Colony there was no institution of the kind in America, and it is still the only one built along true colony lines; consequently we are interested in its development.

It is evident from the report that all persons having epilepsy are not fit subjects for colony life, for it seems quite conclusively shown that many of them are so unsound in mind as to make it, not only useless, but dangerous to permit them to live in an institution in which complete liberty is the privilege of every patient. The study of the mental condition in 1,070 cases, grading them as "good," "fair," "feeble-minded," "imbecile," "idiot," and "insane," and the analysis of the study that follows give some idea as to the class of epileptics which can be successfully colonized and that which cannot.

It would seem that more good could be done if the colony could receive patients whose dis-

ease was not of such long standing. Only 1½ per cent of the entire number had been epileptic less than a year before admission; while in the vast majority of cases the disease had existed for from five to forty years and over.

The study of "The Causes of Epilepsy," analytically made in over 1,000 cases, is of value, for one thing, in showing the great importance that hereditary factors seems to play; and, if there is anything to be learned from such a study, it ought to be the necessity for seriously considering the question of placing restrictions of some sort on the marriage and intermarriage of such people.

The report shows the treatment of patients to be along the broadest possible lines, and this is as it should be, when we remember that the epileptic and his disease should be regarded as a unit and that good results can come only from a recognition of this fact and the treatment of the individual and his disease at the same time.

We note the absence of any enthusiasm in reference to the surgical treatment of epilepsy. At the Colony they seem to think that the genuine disease is not so circumscribed a thing that it can often be removed by surgical intervention. Reference is made to the possible value of serotherapy in the treatment of selected cases, and we expect shortly to publish in the Medical News the Craig Colony Prize Essay on this subject by Dr. Carlo Ceni of Italy.

It is also pleasant to note the freedom of the report from the usual list of long cut-and-dried statistical tables that we have always thought took up much valuable space in such reports, without imparting any knowledge of a useful and practical kind.

The report speaks hopefully of the work of the year and progress made in the treatment, education, occupation and classification of patients. It has been learned that, without provision for occupation and classification, any scheme of this sort must fall far short of attaining the ideal. The *per capita* cost is given at $164.46 for the year, which to us seems very low, considering the scientific and educational work that is done, and we hope that economic reasons at Albany may not reduce it any further. The Colony now has a population of 750 patients, while new buildings are to be opened shortly for 100 additional patients.

THE BOGEY STATE.

It does not speak well for the tender mercies of the State that the people are afraid to trust the care of their helpless ones to its political visitations. Despite the would-be pacification in the altered terms of the Brackett-Rogers Bill, the fact remains that it abolishes the local Boards of Managers of the State Hospitals for the Insane; and the State Commission in Lunacy threatens like a Bogey to swallow the control and leave no trace behind it of that excellent system that has been the pride of the State.

The scare is real. It has taken one hundred people to Albany to protest against the Bill. It has called forth decided opposition from the most influential clergymen in the State. It has brought out a storm of opposition in the daily press; and it has agitated every one who knows anything about the control of an institution under the board of manager system versus the control by a commissioner. We venture to express an opinion that the present Commissioner of Lunacy was not aware that his unsullied reputation would be used as a cat's-paw to pull the chestnut of control out of such a ticklish place. We know well that he has no private ends to push and that power would not be abused by him; but once the authority is vested in the State Commission in Lunacy, how long will that office be open to a man who is a disinterested public-spirited physician?

ECHOES AND NEWS.

NEW YORK.

Health Advisory Board Organized.—The Health Department's new Medical Advisory Board has organized by electing Dr. Edward G. Janeway chairman, Dr. T. Mitchell Prudden secretary, and an executive committee consisting of Drs. Janeway, Prudden, Bryant and Brannan. Of the eleven physicians comprising the board, all but one were present at the first meeting.

Reduction in Death-Rate.—A reduction in the city death-rate was again shown last week, when the rate was 20.71, against 24.33 for the corresponding week in 1901. By excluding the deaths of non-residents and of infants under one week, the rate is reduced to 19.56. For the previous week the rate was 21.24. Cases of smallpox numbered eighteen; there were thirty for the previous week, against an average of twelve cases for the twelve weeks immediately preceding.

Opening of the New Lying-In Hospital.—The beautiful new hospital of the Lying-In Society was formally opened and the first patient admitted this week. There are eight floors and 140,000 square feet of floor-space. A tour of the structure reveals many features in the equipment that are unique in hospital building. The dimensions of the structure are 184 feet on Second Avenue, 166 feet on Eighteenth Street, and 83 feet on Seventeenth Street. Light comes from all four sides and through 1,159 windows. In the electrical system there is a device by which the light of the incandescent lamps can be made bright or dim at will. In the cellar are the engine, boiler, pump, and dynamo rooms and the machinery used for ventilating and refrigerating. The basement contains the out-patient de-

partment, autopsy-room, chapel, and fifteen bedrooms. On the first floor are physicians' rooms, library, and executive offices, while the second floor is given up largely to the nurses. The septic department, on the third floor, consists of twelve bedrooms, serving, operating, and dining rooms. Entrance to this isolated ward can be gained only by going through an open corridor. The fourth, fifth, and sixth floors are identical, each containing sixty-two beds for patients. At the foot of each bed is suspended a cradle. In addition to the wards, there are also private rooms for patients. A summer roof-garden and a winter sun-garden, enclosed in glass, are on the seventh floor, overlooking Stuyvesant Park. The new hospital is the gift of J. Pierpont Morgan, who at first gave $1,000,000 for the purpose. The price of building materials then rose and a larger sum became necessary. Thereupon Mr. Morgan increased this gift and the amount he has given to the hospital now amounts to $1,250,000. He has also completely furnished the institution with linen.

Loomis Laboratory Wins.—The decision of Justice Truax of the Supreme Court dismissing the suit brought by the New York University to recover the site and building of the Loomis Laboratory from the Loomis Laboratory Corporation has been affirmed by the Appellate Division. The laboratory had been used by the students of the University for several years and the Trustees of the University contended that although the title was held in the name of the Loomis Laboratory Corporation, the property was impressed with a trust requiring that it be used for the medical side of the University, which in equity was the owner. Col. Oliver H. Payne had given the site and the money for the building and equipment to the late Dr. Alfred L. Loomis, then connected with the University. The name of the donor was kept a secret for a long time. Col. Payne testified in the trial of the case that the University was not named in the transaction with Dr. Loomis. He had given the property and money in trust to Dr. Loomis for a Loomis Laboratory with the idea that the laboratory should afterward be conveyed to a corporation to carry on its work, which conveyance was made as he requested. He testified that at the time he hardly knew that there was such an institution as the New York University. The court says that the use of the laboratory by the University for several years does not establish a trust in its favor, as it was not shown that there was any trust of the sort going with the gift.

No Changes at Bellevue.—The Board of Trustees of Bellevue and Allied Hospitals, which was appointed by Mayor Low this week will assume control on February 1st of Bellevue, Fordham, Harlem, Gouverneur, and Emergency Hospitals. The functions of the Trustees are exactly the same as those which the Commissioner of Charities exercised over the hospitals before the revised charter went into effect. The nature of some of the general problems of administration has been made familiar to the public by the official or unofficial inquiries made from time to time. The treatment of the insane pending examination for admission to the State hospitals, the fees of the Examiners in Lunacy, the alleged hurried transfers of dying patients from other hospitals to Bellevue, the prompt issuing of notices of deaths, the alleged private "deals" between morgue attendants and outside undertakers, and the improvement of the old buildings are among them. The Trustees wish to have it made known that they have no appointments to make. The entire subordinate staff of the hospitals is protected by civil-service rules, and, moreover, there are no important vacancies to be filled.

Clergymen's Protest Against Changes in the Control of the Insane.—The following protest against the proposed change in the laws affecting the control of the insane has been sent to Gov. Odell:

"To the Governor of the State of New York:

"Sir: We, the undersigned, ministers of religion in the City of New York, unite in protesting against the proposed change of the laws respecting the care of the insane.

"It will centralize all administration, which experience and philosophy unite and declare should be in a democracy as far as possible localized; it will deprive the State of the voluntary, spontaneous service of a considerable number of men and women of large experience and philanthropic character; it will tend to lessen public interest in the charitable work of the State, which ought to be increased rather than lessened; and it will build up a service in the hospitals which will be liable to change with every change of political administration. In our opinion there are no corresponding advantages to counterbalance these evils. The authority now possessed by the central body, the Lunacy Commission, is entirely adequate to prevent local extravagance." This protest is signed by Bishop Potter and a dozen or more of the most prominent clergymen in the city.

Beneficial Work of Consumers' League.—The Consumers' League, of which Mrs. Nathan is the president, showed at its annual meeting, held on January 23d, that it had accomplished important reforms in the matter of sanitary regulations in the manufacture of garments and in the proper and healthful provisions for women employed in stores. The cordial coöperation of the new Board of Health was shown in the fact that Dr. Lederle was one of the speakers. He announced that he was prepared to enforce stringently the Mercantile Employees' Law which has existed since 1897, but which has been practically a dead letter through non-enforcement.

The "Bracket Bill" Denounced.—At a special meeting of the Eastern Medical Society of the City of New York, held at the Educational Alliance on January 24, 1902, Dr. Wm. S. Gottheil introduced a resolution emphatically protesting against the "Bracket Bill" to regulate and legalize the practice of Osteopathy. The resolution was seconded by Dr. A. E. Isaacs and the secretary was directed to send a copy of the resolution in full to the Judiciary Committee of the Senate.

Mount Sinai Hospital Work.—At the annual meeting of the Directors of Mount Sinai Hospital yesterday the old officers were reelected, with the addition of electing David Wile as Second Vice-President. The annual report showed that 6,369 people had applied at the hospital during the past year for treatment. There were 2,386 free patients and 600 pay patients admitted. Because of lack of room 430 people were refused admission. The number or accident cases admitted, which were not included in the foregoing, was 523. There was a daily average of 211 patients. The total number of patients since the institution was founded, in 1852, is 70,537. In the dispensary there were 83,955 consultations, and 80,064 prescriptions were filled. The daily average of consultations was 276. The total receipts for the year were $136,087 and the expenditures $138,087. The institution has $140,000 invested in bonds and mortgages; cash on hand $11,000 and has a building fund of $1,294,281. The Directors reported that they received $38,000 last October in the form of a donation from a gentleman and his sister who were not of the Hebrew faith. They gave the money in recognition of the non-sectarian work of the institution.

Wreck of the Manhattan Eye and Ear Hospital.—At the time of the explosion in the subway, on January

27th, there were sixty patients in the Manhattan Eye and Ear Hospital. This hospital is directly opposite the subway works, and is less than sixty feet from the mouth of the shaft. Almost every patient, nurse, and interne suffered from the shock or was cut by falling glass. Every window was shattered, the big skylight was smashed, and several doors were dislodged from their hinges. The patients were removed immediately from the hospital, and most of them sent to the Eye and Ear Infirmary. The hospital is untenable and will be abandoned entirely. Most of the plaster is shaken from the ceilings in the rooms nearest the street, and one patient, who lay in bed helpless, was covered from head to foot with the mass that fell from the walls about him.

Stony Wolde Sanatorium.—The first annual meeting of those interested in the establishment of the Stony Wolde Sanatorium was held on the morning of January 22d, at the residence of Mrs. George F. Shrady, 8 East Sixty-sixth Street. The President, Mrs. James E. Newcomb, read a report giving the results attained since the organization was founded, a year ago, to provide a sanatorium for the treatment of persons suffering from incipient tuberculosis who are unable for pecuniary reasons to procure proper climatic treatment. To carry on the work, ten auxiliary associations have been formed in New York City and suburbs which have a membership of 500. Through these auxiliaries more than $48,000 has been raised for the sanatorium which will be built in the near future. The Lake Kushaqua property where the institution will be situated was bought last September. It is in Franklin County at an elevation of 1,730 feet above the sea, and comprises about 1,200 acres.

Consumptive Hospital Plans.—The Trustees of the new State Tuberculosis Hospital held their annual meeting in Albany, on January 22d, and reelected the old officers, with Howard Townsend of New York as president. The Trustees called upon the Governor and paid their respects, after which they continued their meeting, devoting the day to the completion of plans for the hospital buildings and to the closing of the contracts for the purchase of the Raybrook site.

Cold Brooklyn Cars.—Dr. Joseph H. Raymond, Health Officer in charge of the Borough of Brooklyn, has written to the Health Office authorities in Manhattan to secure their aid in the adoption of an ordinance by the Aldermen that will be binding on the Brooklyn Rapid Transit Railroad Company in the matter of keeping their cars comfortably heated in cold weather. Dr. Raymond obtained on January 25th statistics of local car temperatures by assigning several of his sanitary inspectors to take trips over the various lines running between Newtown Creek and Coney Island and from the river front to Ridgewood. The inspectors found the temperature inside the cars ranging from 24 degrees, which is 8 degrees below freezing, to 40 degrees, which is 8 degrees above freezing. The highest temperature discovered in their travels at any time on any of the Brooklyn Rapid Transit cars was 54, and unofficial figuring on their returns developed an average temperature of about 34 degrees inside the cars, just 2 degrees above freezing. The Health Office inspectors, on their rounds, ascertained that the four lines of the Coney Island and Brooklyn Railroad, in which Police Commissioner John N. Partridge is said to be interested, and which are operated in competition with the Brooklyn Rapid Transit, provided an average temperature of over 52 for its patrons. No fault is found with this company.

To Protect Dairy Products.—A bill designed to prevent the adulteration of dairy products has been introduced by Senator Slater. It provides that no person shall add to any dairy product intended for human food or drink any substance containing formaldehyde or salicylic acid, or other harmful substance or substances, nor shall any product containing such acid be offered for sale.

School for Milk-Dealers.—Because he has received numerous complaints from retail milkmen with relation to the practices of the wholesalers, who, they claim, are busy adulterating the milk, Dr. Raymond of the Health Department in Brooklyn has decided to establish a school of instruction. He has applied to Borough President Swanstrom for the use of the Court of Special Sessions, and when that is given will have Dr. Williams, one of his assistants, demonstrate the use of the lactometer, so that the men themselves can detect any adulteration, and make specific complaint to the Department.

Warning Abattoir Owners.—Following up the principle that induced the Health Board to deny the application of Swift & Co., for permission to build an abattoir on Forty-fourth and Forty-fifth Streets, east of First Avenue, a letter has been sent by Commissioner Lederle to all the more important companies which have slaughter-houses in that section, notifying them of complaints of constant annoyance from existing slaughter-house plants and warning them that the condition of affairs complained of must be remedied before the advent of warm weather. Commissioner Lederle reminded them that they were acting under a permit revocable at the pleasure of the Board of Health, and that all such permts would be revoked whenever the Board of Health should become satisfied that conditions in operation in the slaughter-houses were prejudicial to the public health.

New York Academy of Medicine.—A stated meeting will be held Thursday, February 6th. The following program is anounced: Resolutions on Action of Treasury Department Declaring Pulmonary Tuberculosis a "Dangerous Contagious Disease," and Debarring Consumptive Aliens, Rich and Poor, from Entering the Country. Paper on the Phenomenon of Inhibition, Its Possibilities in Pathology, Especially in Its Relations to the Diseases of Myxedema and Exophthalmic Goiter, by S. J. Meltzer. Discussion will be taken part in by Drs. Charles L. Dana, Isaac Adler, M. Allen Starr, William H. Thomson, F. Peterson and William Hirsch.

Brooklyn Medical Society.—The following were elected officers of the Brooklyn Medical Society at the annual meeting held in January, 1902: President, William H. Haynes, M.D.; Vice-President, Malcolm E. Parrott, M.D.; Recording Secretary, Hugh E. Rogers, M.D.; Corresponding Secretary, Alfred Bell, M.D.; Treasurer, Albert H. Brundage, M.D.; Librarian, Lewis E. Meeker, M.D.

A Suit for Malpractice Against Dr. Thos. H. Manley.—In Part IX. of the New York Supreme Court, before Judge McLean, an action was brought by Selina Schneider against Dr. Manley, for alleged malpractice in the unnecessary removal of a joint of the thumb. After a trial lasting two days the jury deliberated five minutes and brought in a unanimous verdict for the defendant. The most unfortunate feature of the affair was the fact as brought out in the evidence, that the prosecution was instituted by the advice of a fellow practitioner.

PHILADELPHIA.

Smallpox Statistics.—For the week ending January 25th there were reported 90 new cases of smallpox

and 19 deaths, an increase of 8 cases and 3 deaths over those of the previous week. There are now 443 cases under treatment.

Increase in Typhoid Fever.—The cases of typhoid fever for the week ending January 25th were 117, an increase of 36 over the previous week. Much of the increase comes from West Philadelphia. The water supply is worse there than in any other section of the city.

Isolation Hospitals.—Dr. J. Madison Taylor, who has labored indefatigably toward securing pay hospitals for contagious diseases, in a recent statement to the public admits that the organization for that purpose has met with but little encouragement. He states that the rapidly-increasing number of well-to-do people who live in apartments or hotels makes an isolation hospital an absolute necessity and its realization a matter of time.

Patients Owed Him $50,000.—Dr. H. U. Umsted died January 25th at Phoenixville, where he had practised medicine for fifty-five years. At the time of his death he had $50,000 in uncollected bills on his books.

Officers of County Medical Society.—The annual election held January 15th resulted as follows: President, Dr. Thomas H. Fenton; Vice-Presidents, Drs. F. M. Perkins and J. Chalmers Da Costa; Secretary, Dr. Elwood R. Kirby; Assistant Secretary, Dr. William S. Wray; Treasurer, Dr. Collier L. Bower; Censor, Dr. W. Joseph Hearn.

Dairy and Food Division of the Department of Agriculture.—At a recent meeting of the State Board, Commissioner Cope presented a statement of the work done in 1901. The number of samples of oleomargerine, butter, cheese, milk, etc., analyzed was 3,019. Of the suits brought against dealers there were 1,159 oleo cases and 192 of other products.

Philadelphia County Medical Society.—At the meeting held January 22d, the guest of the evening was Major Louis A. La Garde, Surgeon United States Army. Dr. La Garde gave an instructive talk on "Gunshot Wounds of the Knee by Reduced Caliber Projectiles." Sixty-two cases were reported. The mortality-rates were compared and attention called to the difference in the number of amputations. Many skiagraphs were shown, an interesting one being that of a soldier shot by a Filipino, the ball entering behind the ear and lodging in the tongue. This is the fifth case of the kind on record. In discussing the subject Dr. W. L. Rodman said that in wounds met with in civil practice he seldom amputated unless there was extensive injury to the vessels or nerves.

South Branch County Medical Society.—The meeting of January 24th was devoted to a symposium on tuberculosis. Dr. P. S. Donnellan spoke of laryngeal tuberculosis and its treatment. He stated that the physician should take a more hopeful view of these cases than is generally held. A strictly routine treatment should be avoided. For the ulcers which develop there is nothing better than lactic acid. Dr. J. R. Young spoke of the diagnosis and treatment of tubercular arthritis. Dr. Chas. P. Noble spoke of abdominal tuberculosis. Dr. A. O. J. Kelly spoke of the diagnosis of pulmonary tuberculosis. He mentioned four forms in which tuberculosis first manifests itself, the pleuritic, the hemoptytic, the bronchitic, and the insidious. The early diagnosis of the latter is of great importance. Symptoms suggesting this condition are gastric disturbances, progressive weakness, and a peculiar pallor. Changes of temperature are more common in early involvement than is generally supposed. In suspected cases the temperature should be taken every two hours for one or two weeks. The acceleration of the heart's action or its instability, especially under nervous excitement, is another point to notice carefully. Tubercle bacilli are not found in the sputum in the very early stages, but they are present almost as soon as demonstrable signs occur. As to tuberculin, Dr. Kelly finds it especially valuable as an aid to diagnosis in patients who have recently recovered from an attack of pleurisy. He has used it in many cases in hospital practice and the reaction has aided in making an early diagnosis of tuberculosis.

Vaccine Examinations by State Board of Health.—Microscopical and bacteriological examination of the vaccine lymphs on sale in Philadelphia have been made by the State Board of Health. No virulent bacteria were found. The number of bacteria in each varied greatly in the different makes of virus, ranging from 36 to 801 in dry points, from 24 to 63 in glycerinated points and from 2 to 11 in tube virus. Attention is called to the notable decrease in the glycerinated tubes as compared to the glycerinated and dry points. In general the quality of lymph shows a marked improvement in the number of bacteria over the same lymphs as tested in 1896 by the same bacteriologist.

Philadelphia Pediatric Society.—The following officers have been elected for the ensuing year: President, Dr. S. McC. Hamill; Vice-Presidents, Drs. D. J. M. Miller, J. H. Jopson, A. A. Eshner; Treasurer, Dr. H. B. Carpenter; Secretary, Dr. C. H. Weber; Recorder, Dr. D. L. Edsall.

CHICAGO.

Warden Healy Stops Operation.—An operation being performed upon a woman in the general clinic at the Cook County Hospital, January 23d, was stopped by Warden Healy, and the patient removed to a private operating-room, away from the view of medical students. The Warden recently gave an order that women should not be publicly exposed while undergoing perineal and uterine operations, and he intends to enforce it.

Chicago Laryngological and Climatological Society.—At a meeting of this Society, held January 21st, the following officers were elected: President, Dr. M. R. Brown; Secretary-Treasurer, Dr. John Rhodes; Members of the Council, Drs. William E. Casselberry, Edward T. Dickerman, and Dr. Otto L. Freer.

To Transfer Insane.—The superintendents of the State Hospitals for the Insane held a meeting at Springfield January 23d to confer with the State Board of Charities with reference to the transfer of inmates of their institutions to the Asylum for the Incurable Insane at Peoria, which will be opened February 20th. The employees' quarters, and the light, heat and storage plants of the Peoria asylum are sufficient to allow the accommodation of 3,000 patients, but the cottages in course of construction will not hold more than 700, and only 300 can be cared for at the opening. Under the law the incurable insane now in other State Hospitals must first be transferred to the new institution. The 300 to be transferred will be taken from the hospitals at Kankakee, Elgin and Jacksonville—100 from each—and special arrangements will be made with the railroad companies for the transfer. In selecting patients for transfer from their institutions the superintendents will apportion them as nearly as possible according to the ratio of quarters assigned the counties in their respective districts. Upon this basis 59 Cook County patients from Elgin and 65 from Kankakee will be sent to Peoria, thus giving the county immediate room in Elgin and Kankakee for 124 inmates who are at Dunning. As fast as the capacity is in-

creased in Peoria transfers will be made from the hospitals at Watertown and Anna.

Scarlet Fever.—It is impossible for the Department of Health to maintain isolation and to enforce preventive measures in every household, probably a thousand, in which there is scarlet fever at the present time. This disease had increased 35 per cent. during the first eighteen days of January over the last eighteen days of December, while diphtheria has increased less than 10 per cent. in the same period. The figures of mortality from the two diseases are even more striking—34 per cent. decrease in the deaths from diphtheria and 25 per cent. increase in the number of scarlet-fever deaths. Unfortunately there is as yet no antitoxin for the latter disease, and only great care in preventing contact with cases until all signs of scaling have disappeared and then thorough disinfection of person, clothing and sickroom can be relied on to restrict its spread.

Very Little Smallpox.—The Health Department is thus far entirely satisfied with its smallpox record. There have been but 18 cases this month and only 30 all told since August 12, 1901. The fact that no case has occurred among hotel and restaurant people, employees of stores and business places and others brought into personal contact with visitors speaks volumes for the intelligent appreciation of the protection afforded by modern methods of vaccination in Chicago.

Chicago Neurological Society.—At a recent meeting of the Chicago Neurological Society, Dr. H. H. Donaldson gave the description of a new chart drawn by Mr. Davis to represent the areas of the gray and white matter in the human spinal cord at the level of each spinal nerve. The base line represents the average length of the adult cord and is divided into thirty-one parts, each having the length of the corresponding segment. The data for the areas of the cross-sections were taken from Stilling's tables. The new features in this chart are the division of the base line into lengths equal to those of the corresponding segments, and the use, for the areas of the cross-sections, of data derived from the measurement of the adult cord. The diagram at present found in the text-books is based on Stilling's measurements of the cord of a five-year-old child; while the base line is divided into equal intervals for the segments, thus failing to give the measurements for the adult cord, and disturbing the relations of the curve which is presented. Dr. Ronaldson next presented some results obtained by Mr. Hatai from his studies on the spinal ganglion of the white rat during the growing period. Four rats were used, their body weights being 10, 24, 63 and 167 grams respectively. In each rat the number of cells in the ganglion and the number of fibers in the dorsal nerve-roots of the sixth cranial, fourth thoracic, and second lumbar was determined. On comparing these numbers thus obtained it was possible to draw the following conclusions: (1) In the spinal ganglia the number of cell-bodies is constant between birth and maturity. There is, of course, some individual variation in this number. (2) The fibers of the dorsal nerve-roots are more than twice as numerous in the 167-gram rat as in the 10-gram rat, and the intermediate weights show intermediate numbers in the roots. (3) Since this is the case, it follows that the ratio between the number of cells in the ganglia, as compared with the number of fibers in the dorsal nerve-roots, steadily decreases. In the youngest stage there may be as many as eleven cells in the ganglion for each fiber in the dorsal nerve-root, while in the case of the most developed nerve there are still 2.7 cells for each fiber. It appears that the new fibers are formed by the outgrowths of cells present in the ganglion from the earliest stage. Studies on the general activity of the rat show that they are most active when weighing from 25 to 35 grams, and, therefore, at a time when the number of fibers in the dorsal nerve-roots is still very incomplete.

Health of Chicago.—Doctors are unusually busy and the death-rate still declines. It is not meant, however, to flatter the profession unduly by implying that the latter is the result solely of the former. There is a vast amount of sickness in the city; but, fortunately, the prevalent maladies—except scarlet fever—are of a mild type. The 480 deaths from all causes recorded last week give an annual rate of only 13.73 per thousand of population, a reduction of about seven per cent. from the rate of the previous week and of 3.8 per cent. from that of the corresponding week last year. There has been a notable increase in the demands upon the main and sublaboratories for bacterial examinations since the appeal was made for a more general resort to these means of determining the character of obscure symptoms, especially those of influenza. Fully 60 per cent. of all examinations reveal the presence of the bacillus of this disease, either pure or associated with other germs, chiefly those of pneumonia. But the number of examinations called for is still wholly disproportionate to the prevalence of the disease. The Department renews its warning as to scarlet fever and the duty of parents to aid in preventing its spread by proper isolation of their own children when afflicted and to guard the well ones against association or contact with the sick. A scarlet-fever case is dangerous until all "scaling" has entirely disappeared—usually about six weeks after it begins. Physicans may materially assist by advising parents on this point and by discontinuing premature requests for disinfection. Disinfection does not disinfect while the child is still scaling. Only eight new cases of smallpox were discovered during the week—two imported from Wisconsin and both sent to the hospital in advanced eruptive stage; three were contracted from previous city cases and the origin of the remaining two is as yet unknown. Fortunately, the occupants of the hospital are properly protected by recent vaccination and no apprehension is felt from the cases that stray in or are sent there. Of the eight cases five had never been vaccinated at all and the remaining three, aged twenty-nine, thirty and fifty years, respectively, had only imperfect traces of vaccination in childhood, never repeated. The discovery on the 19th ult. of three cases of the disease in Highland Park, twenty-three miles north of the city, and one at Glencoe, four miles south of the Park, led Chief Medical Inspector Spalding to make a visit of investigation. He traced the cases unmistakably to a visitor from Ripon, Wis., just recovering from so-called "chicken-pox." None had been vaccinated. By Dr. Spalding's advice, general vaccination and revaccination are being enforced in both localites. The infection centers are steadily getting nearer Chicago and no unprotected person in the city can afford to take any chances. Again: Get vaccinated. The cleansing effect upon the atmosphere of the snowfall of January 21st is shown by the following: On the 18th ult. shallow glass dishes containing the usual preparation favorable to the growth of atmospheric germs were exposed to the air for three minutes in ten different localities within the half-mile bounded by South Water, State and Adams Streets and Fifth Avenue. After seventy-two hours' incubation these showed an average of 630 colonies of growing germs—the greatest number, 1,050, being found at the northeast corner of Dearborn and Washington Streets, a few feet above the street level; the least, 330 in the south court between the City Hall

and the County Building; and the next fewest, 335 on the roof of the City Hall, about 130 feet above street level. On the 21st ult. snow fell to the equivalent of 0.28 of an inch of rain and the experiment was repeated on the 22d. The average colonies from these latter exposures numbered 66, ranging from 19, at the southeast corner of La Salle and South Water Streets, to 180 at the southwest corner of Washington and Fifth Avennes. The amosphere was nearly 90 per cent. purer on Wednesday after the snowfall than it was before. Chicago needs snow; the records of the Weather Bureau fail to show a period of dryness equal to that which has now been continuous since the middle of last October. The public water supply has averaged fairly good during the week, but it is still to be regarded with suspicion as a drink for the young and non-immune to typhoid. Unlike the presumption of the law that a man is innocent until proved guilty, hydrant water must be considered dangerous until proved to be safe. The Department's warnings too often reach the public after the event. Boil all water intended to be drunk by the young, at least.

CANADA.

The Toronto Western Hospital.—This hospital has arranged tents on its lawns so as to accommodate fifteen consumptives.

A Health Officer Contracts Smallpox.—Dr. Hamilton, the local Medical Health Officer of Cornwall, Ont., has contracted smallpox while in the discharge of his duties.

McGill University and Newfoundland.—Speaking at the banquet of the New England Graduates' Society of McGill University on the evening of January 23d, at Boston, Dr. Petersen, the Principal of McGill, referred to the excellent work being done by an affiliated college at Vancouver, B. C., and to the prospects of a similar institution being established in Newfoundland.

Appointments.—Dr. S. B. Jones has been appointed assistant in clinical laboratory work at the Royal Victoria Hospital, Montreal. Dr. Lachapelle has retired from the mayoralty contest in Montreal. Dr. John Hayes has been elected mayor of Richmond, Quebec.

New Medical Buildings.—Much progress has been made in the arrangements for the new medical buildings which are to be erected for the growing requirements of the Medical Faculty of Toronto University. It has been agreed that the Arts Faculty will bear two-fifths of the cost and the Medical Faculty the balance. The new building will be situated in the Queen's Park near the other buildings of the University. This will be the final act in centralization as the old building of the medical faculty was distant a mile from the University.

Cottage Hospitals for the Northwest.—The idea originated by Her Excellency, the Countess of Minto, of establishing cottage hospitals in the sparsely-settled districts of the Canadian Northwest as memorials to our late beloved Queen, is taking shape, and already two are in course of erection and a third is under consideration. The women of the Dominion are coöperating with Her Excellency and collecting books for 25, 50 cents and $1.00 are being issued.

To Reform the Ontario Medical Council.—Dr. Jessop, one of the members of the Legislature, has introduced a bill seeking to reform the Ontario Medical Council. The Council as at present organized consists of thirty members, five of whom represent the Homeopathic practitioners of the province, eight the non-elected appointees of four medical colleges, connected with Toronto University, Trinity University, Queen's University and the Western University at London. The other seventeen are elected by the general practitioners of the Province. Dr. Jessop claims that there are only forty Homeopathic practitioners in the Province and they have five representatives, whereas the general or regular profession numbers 250 for each representative. His bill proposes to abolish the Homeopathic and the appointed representatives on the Council and to have the entire thirty members elected by the general profession throughout the province.

Quarantine on the Pacific Coast.—A new quarantine order has been issued from the office of the Director-General of Public Health at Ottawa and it refers to a change in the quarantine arrangements affecting the Empress line of steamers plying between Vancouver and the Far East. Under the new order all steamers will be obliged to touch at the Williams Head station only when contagious diseases have developed on the voyage. Before, every steamer was obliged to anchor for four or five hours whether contagious diseases were on board or not.

A New Women's Hospital for Toronto.—For two years the corporation of the Women's Medical College has been endeavoring to raise the funds for a hospital in connection with the college, but so far the work has been educational and organization for the purposes of raising those funds and a good foundation has been laid for the collection thereof. Dr. Minerva Greenaway presented the report of the dispensary in connection with the college. This dispensary is nearing the close of the fourth year of its establishment and during that time there have been registered 9,000 patients, by far the larger number of these being women. Thus, the need of such a hospital in connection with the work of the Women's Medical seems to be emphasized.

Royal Victoria Hospital, Montreal.—The annual meeting of the Governors of this institution was held during the past week when it was stated that plans are now being prepared for an extension to the hospital with provision for an operating-room for the gynecological department. During the past year 2,579 patients were admitted to the hospital and of this number 1,254 were free patients. In January, 1901, there were 194 patients in the institution. The death-rate for the year has been 4.42 per cent. In the out-door departments the total number of patients treated was 3,601. The income for the year amounted to $130,738.40; the expenditure, $112,280.20.

New Appointments.—The following have recently been appointed on the staff of the Royal Victoria Hospital, Montreal: Dr. A. G. Nichols, Assistant Pathologist; Dr. G. P. Girdwood, Director of the Medical Electrical Department of the hospital; Drs. H. B. Cushing and F. M. Fry, Clinical Assistants in Medicine; Drs. A. Shirres and A. A. Robertson, Clinical Assistants in Neurology; Dr. E. A. Archibald, Clinical Assistant in Surgery; Dr. F. W. Harvey, Clinical Assistant in Ophthalmology; Dr. W. H. Jamieson, Clinical Assistant in Laryngology; Dr. H. B. Yates, Assistant in Bacteriology; Dr. A. A. Bruere, Director of the Clinical Laboratory; Dr. H. B. Cushing, Medical Registrar.

GENERAL.

The Medical Director of the Louisiana Purchase Exposition.—The post of Medical Director of the St. Louis World's Fair has been filled by the appointment of Dr. Leonidas H. Laidley. Dr. Laidley is a man of thirty-five, a successful practitioner and a medical teacher in St. Louis. He is professor of gynecology and pelvic surgery in the Marion Sims-Beaumont College of Medicine. In addition, he is surgeon to the

Protestant Hospital, consulting surgeon to the Female Hospital, and a leading member of the St. Louis Medical Society and other medical organizations. He was a delegate to the British Congress in 1883, and while abroad visited the hospitals of the principal cities. When the Louisiana Purchase Exposition Company was organized he was one of the incorporators.

Temporary Injunction Against Smallpox Hospital.—Vice-Chancellor Emery has granted a temporary injunction restraining the Mayor and Council of East Orange from receiving patients at the smallpox hospital that is being built on Clinton Street in that city.

Smallpox in Princeton.—One student in Princeton University has smallpox. The authorities are taking every precaution to prevent the spread of the disease among the students, who are being vaccinated as rapidly as the work can be done. There are four other cases of smallpox among the residents of the town.

More Money for Lakeside Hospital in Cleveland.—Samuel Mather, who has given thousands of dollars to Lakeside Hospital, has nearly completed the arrangements for a gift of about $40,000, which is offered to the Hospital Board under certain conditions, the compliance with which will be a small matter.

The St. Louis Medical Society of Missouri.—On January 25th the meeting of this Society was opened with a paper on "Ophthalmoscopic Examinations in Nephritis" by Dr. Meyer Wiener. This was followed by a discussion by Drs. Carl Barck, Dr. W. A. Shoemaker, and Dr. Hugo Summa. A paper on "Ear Complications and Sequelæ of Influenza" was read by Dr. M. A. Goldstein and discussed by Drs. J. B. Shapleigh, L. Caplan, and Dr. F. M. Rumbold.

Medical Society of the District of Columbia.—At a recent meeting of the Medical Society of the District of Columbia the following officers were elected for the present year: President, Dr. Samuel S. Adams; Vice-Presidents, Drs. J. W. Chappell and A. R. Shands; Treasurer, Dr. C. W. Franzoni; Corresponding Secretary, Dr. Thomas C. Smith; Recording Secretary, Dr. Francis P. Morgan; Librarian, Dr. Edwin L. Morgan.

Prophylaxis of Syphilis in France.—A committee has been formed for the study of questions relating to the prophylaxis of syphilis and venereal diseases in France, and also to investigate the frequence of these maladies, institutions for their treatment, and the best means, legislative and administrative, to prevent their propagation.

Italian Surgical Congress.—The next Congress of the Italian Surgical Society will be held in Rome during the month of March.

Statistics of Rabies.—Since 1886, 26,165 people who had been bitten by mad dogs have been treated at the Pasteur Institute in Paris. Of this number, but 107 died.

The Transvaal War and Insanity.—It has been noticed in England that soldiers returned from South Africa suffering from extreme nervous excitement and insomnia. The increase in the number of insane in 1901 is attributed largely to the Transvaal war.

Physicians and Apothecaries.—In Germany there is one physician to 2,058 people, but only one apothecary to 10,363.

How They Regulate Tunnel Air in Paris.—The Paris City Council has had analyses made of the air in the tunnel of the new rapid-transit railroad, and has found an excess of carbonic acid gas. Consequently, it has summoned the management of the railroad to appear before it and show how it is going to purify the air.

Smallpox Epidemic in London.—Sir James Crichton Browne, the eminent English physician and specialist in mental diseases, dealt with the prevailing smallpox epidemic in London, the other day, in an address, which he delivered before the British Sanitary-Inspectors' Association. He said that, although the visitation was cause for anxiety, yet there were now means for combating it, which did not exist formerly, and he dwelt particularly upon the protective power of vaccination, when properly performed. He had become a convert, he admitted, to the law which did not enforce the operation in the face of conscientious objections, but he expressed the conviction that persons who refused to be vaccinated ought to be subjected to additional obligations. "The avoidance of vaccination," he said, "should be made appreciably more troublesome and expensive than compliance with it, since, for one child unvaccinated, owing to conscientious objection, there were at least a hundred or so disabled by the ignorance, indolence, or carelessness of their parents." He approved of the suggestion of a system of international notification of smallpox, and admitted that sanitation was a factor in preventing its spread. But when all was said and done, he declared, there was no substitute for vaccination in relation to smallpox, though it might have its auxiliaries.

Prof. Virchow Growing Weaker.—The condition of Prof. Rudolf Virchow, the eminent pathologist, who injured his thigh by a fall when alighting from a street car in the early part of this month, causes apprehension among his physicians. Prof. Virchow is growing weaker as a result of his accident.

Obituary.—Dr. Charles George Sproull died on January 25th, at Dr. William T. Bull's private sanitarium at 33 East Thirty-third Street, New York. He was stricken with paralysis of the intestines last Wednesday and was removed from his apartments in the Beverwyck in West Twenty-seventh Street. He failed rapidly and early on Saturday morning it was decided that an operation was necessary. Dr. Sproull was thirty-four years old. He was a graduate of Princeton University and of the University of New York. He was for two years house physician of Bellevue Hospital.

Dr. S. Seabury Jones died from pneumonia at his home, No. 712 Madison Avenue, on January 23rd, after an illness of three days. Dr. Jones, who was fifty-five years old, was born in Oyster Bay, Long Island, and had been practising medicine in New York since 1869. He was a graduate of the New York University. He was a member of the Academy of Medicine, the Manhattan Medical and Surgical Society, and the Lenox Society. He was consulting physician at both the Workhouse and Almshouse.

Dr. Francis Clemens, Jr., of Paoli, Pa., was drowned on January 22d in Ridley Creek, Westchester, Pa. In company with his brother he attempted to cross the stream, which had been swollen by heavy rains. His carriage was overturned and Dr. Clemens was swept away. His body has not yet been recovered. His brother was rescued by a farmer who heard his cries for assistance.

Dr. Andrew J. Hines died January 21st, at Doylestown, Pa., at the age of seventy-six. He graduated from Jefferson Medical College in 1853, and was the oldest practising physician in Doylestown.

Dr. Lachlan Tyler, fifty years old, of No. 303 West One Hundred and Twentieth Street, New York, died on Sunday, January 26th, at the Post-Graduate Hospital, of appendicitis. Dr. Tyler was the son of President John Tyler, tenth President of the United States, and for many years was connected with the Depart-

ment of Health of New York. A brother is now President of William and Mary College, at which both Dr. Tyler and his father were educated.

Dr. Dominick George Bodkin died on Sunday night, January 26th, at his home, No. 290 Clinton Avenue, Brooklyn, after a long illness. He was well known as a physician in Brooklyn, where he had practised for thirty-five years. He was born in County Galway, Ireland, in 1833, coming to this country with his parents when he was nine years old. He served in the Civil War as an assistant surgeon in the corps commanded by Gen. Canby. He was a delegate to the International Medical Congress held in Russia some years ago. He was also a member of the New York State Medical Association, the Kings County Medical Society, the Mutual Aid Physicians' Association, the Columbian Club, the Catholic Benevolent Legion, and other organizations. He was also for many years on the medical staff of St. Mary's Hospital.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, January 18, 1902.

A GREAT SCHEME OF CANCER RESEARCH—THE FORTHCOMING ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION—THE MIDWIVES QUESTION.

Since the dispatch of my last letter the movement against cancer to which reference was there made has taken shape. The initiation of the project is attributed to Mr. Henry Morris, Senior Surgeon to Middlesex Hospital, who is said to have perfected a scheme for establishing a fund to provide for the prosecution of research in the matter of cancer. According to an evidently inspired communication which appeared on January 16th in an evening newspaper, the objects of the fund are to provide, equip, maintain, and endow laboratories to be devoted exclusively to cancer research; to endow a directorship of research; to provide paid assistants to the director, research scholarships, and grants in aid of cancer research within the United Kingdom, etc.; to assist in the development of the cancer department of Middlesex Hospital and of any other hospital where a special cancer research department may be provided; and generally to provide means for systematic investigation into the causes, prevention, and treatment of cancer. The promoters of the scheme propose (should the object of the fund be attained by the discovery of the cause and nature of cancer, and of an effective method of treatment) that the trustees, with the consent of the Royal Colleges, shall be empowered to utilize the income of the fund either for equipping such hospitals as they may select with any appliances which may be necessary for such treatment, or for forwarding in similar manner research into other diseases. It is further proposed that the general committee shall include the president and two censors (for the time being) of the Royal College of Physicians of London, the president and two vice-presidents of the Royal College of Surgeons of England, the members of the laboratories committee of the Royal Colleges of Physicians and Surgeons, and one member to be nominated by the Local Government Board. An influential board will be appointed to advise the general committee as to the best means to be adopted in promoting the inquiry and in allocating money. It is estimated that the annual expenditure from the fund will be some £2,250, which will include grants for research, salaries, etc. Among those who have expressed themselves as favorable to the scheme are Lord Lister, Sir William Broadbent, the late Sir William MacCormac, Bart, Sir R. Douglas Powell, Sir Thomas Smith, and Sir John Williams.

From this it will be seen that I was strictly correct in stating that the scheme had taken shape. But it still wants substance, for though Mr. Henry Morris may have "perfected a scheme" for establishing a fund, no fund yet exists, nor does the pious founder show any disposition to come forward. As I told you last week, the Colleges of Physicians and Surgeons, though they have the matter under consideration, have not yet decided to take any action. It will be noticed that in the "officious" communication of which the gist is given above the Royal Colleges are mentioned only in a casual way, while prominence is given to the Middlesex Hospital as the place in which the research may most advantageously be carried out. This indicates that the scheme is, in its "first intention," designed for the greater glory of the Middlesex Hospital of the staff of which the initiator is a distinguished ornament. Other hospitals are not unnaturally urging their claims to participate in any endowment of cancer research that may be secured, and there is thus a serious risk that a scheme big with promise of benefit to mankind may be wrecked by the jealousy of rival institutions. The right solution of the difficulty would be to place the funds at the disposal of the Royal Colleges for the creation of a central laboratory with a special staff working under their control. As a matter of fact the Middlesex Hospital has perhaps less claim than many others to endowment for the particular purpose intended; for although it has wards devoted to sufferers from cancer and a special department for the pathological investigation of cancer, little or no new light on the subject has come therefrom.

The British Medical Association is to hold its next annual meeting in Manchester under the presidency of Mr. Walter Whitehead, a surgeon whose name is doubtless familiar to many on your side of the Atlantic in connection with his operative procedures for hemorrhoids, cancer of the tongue, etc. The prospects of a successful meeting have been seriously jeopardized by the foolish arrogance with which the representatives of Manchester on the Council of the Association endeavored to make that body an instrument for the pursuance of local quarrels and the satisfaction of personal spite. They claimed the right to determine what addresses should be delivered and to select the orators. For the sake of peace probably the matter was left in their hands, and accordingly they decided that the customary Address in Obstetrics should have no place in the program. The pretext alleged for this innovation was that more time would thus be available for the transaction of business. The real motive, however, was speedily apparent. Professor Japp Sinclair, who occupies with great distinction the chair of obstetrics and gynecology in the Victoria University, Manchester, had made himself personally obnoxious to some uncompromising opponents of the legal recognition of midwives, and they saw in the annual meeting an opportunity of revenge. Among the representatives of Manchester on the Council are some of the fiery spirits aforesaid, but though active in "political" agitation they cannot be regarded as in any sense representative of the profession in Manchester. It is, indeed, one of the weak points in the Association that neither in London nor elsewhere do the leading men in the profession take an active part in the conduct of its affairs. Hence a set of nonentities of no importance even locally may cause mischief by ill-judged decisions on questions with which they cannot be trusted to deal. In the present instance the gravest dissatisfaction was excited in high professional quarters in Manchester by the attempt to boycott Professor

Sinclair. His colleagues at once took up his quarrel as their own and determined to have nothing to do with the annual meeting. This would have made the gathering simply a *fiasco*. The President-Elect, Mr. Walter Whitehead, found himself in a difficult position, for he had to make up his mind to throw in his lot either with his colleagues of the University or with the Association. He appealed to the Council to extricate him by throwing over the Manchester representatives who had caused the mischief, and this was finally done.

The midwives question which is at the bottom of the whole thing is likely to come before Parliament in the course of the next few months. The profession has been led into a false position by a small band of intransigents who profess to speak in its name, and the public which is beginning to recognize the necessity of legislation is certain sooner or later to insist on the matter being dealt with regardless of interested opposition.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninety-Sixth Annual Meeting, Held at Albany, January 28, 29 and 30, 1902.

FIRST DAY—JANUARY 28TH.

Inaugural Address.—The President, Dr. Henry L. Elsner of Syracuse reviewed the recent progress of medicine and surgery in his inaugural address. He called attention to the eminent desirability of having harmonious action in all public matters among the medical profession of New York State. The existence of two State medical organizations interferes with this and he suggested that steps should be taken looking toward reunion. As the result of this a resolution was offered empowering the President to appoint a committee to consider and report to the Society as to the advisability of having the President appoint a committee of conference to meet a similar committee to be appointed by the New York State Medical Association to discuss the ways and means of union between the two medical organizations of the State.

Treatment of Goiter.—Dr. Thomas Scully of Rome opened the scientific program with a discussion of the medical and surgical aspects of the treatment of goiter. He considers that parenchymatous enlargements of the thyroid gland may in early stages at times be relieved by internal administration of the iodides. Sometimes injections of iodine or of carbolic acid directly into the substance of the gland give good results. For cystic conditions surgical interference will always be needed. It is well not to delay radical surgical intervention so long that extensive adhesions to the important structures of the neck have taken place. Dr. Scully has found that local anesthesia by means of cocaine is very effective in these cases. The operation as a rule requires less time and there is less subsequent pain and no vomiting to interfere with postoperative conditions and make the patient very uncomfortable.

The Professional Midwife.—Dr. M. J. Lewi of New York said that last year, while some 80,000 births were reported by physicians in New York City, over 30,000 were reported by midwives. This represents about the proportion of obstetrical cases that go to these two classes of attendants in recent years. The problem is a very large one. As the result of the work of ignorant midwives there are blind children crowding the blind asylums and maimed women crowding the dispensaries. As the result of the work of criminal midwives there are thousands of abortions being procured and the system of child-farming, so fatal to the lives of infants, is perpetuated. Something should be done by the representatives of the profession of New York State to prevent these evils. The general public rightly looks to the medical societies in this matter. There is need for the legal regulation of midwives. There should be a law requiring all midwives to be registered and permitting only those to register who have passed a suitable examination and who have attended at least a dozen cases of labor under proper direction. The Legislation Committee of the State Medical Society should be instructed to draw up a bill for this purpose and the influence of this Society should be exerted to secure its passage.

Legal Registration.—Dr. Abraham Jacobi of New York said that the legal regulation of the practice of midwifery by women who are not physicians is a crying need of the times. There will always in large cities and also in country places be need of the services of midwives, and women will employ them. In order properly to control them legislation looking to examination and registration is required. Midwives are not the only ones who perform abortions, and, if members of the profession do so, how much more these irregulars? It is useless to hope for ideal results, and the practical conditions demand that the midwife shall be acknowledged and her proper training encouraged. A resolution was then adopted instructing the Legislative Committee to draw up and present a bill to the Legislature on this subject, embodying the ideas of this discussion.

Human Asymmetry.—Dr. W. S. Ely of Rochester said that there is no absolute symmetry in Nature. French gardeners in attempting to make trees formally symmetrical made them grotesque. In infancy human beings are most symmetrical. Growth, exercise and work soon increase the slight asymmetry always present. Even the skull is asymmetrical and there may be enough difference in the two sides to make fractures difficult of recognition. The general asymmetry of the body is increased by the training for righthandedness. This is unfortunate, as it gives a proper development to only one-half of the body. Dr. Ely suggests that family doctors should discourage the exclusive training of one side of the body only. Some of the spinal curvature so noticeably on the increase in recent years is due to this mistaken notion. The lack of symmetrical training in the past has deprived the majority of mankind of certain faculties and dexterity that would normally have been their due.

Sarcoma of Tonsil.—Dr. Arthur G. Root of Albany described an operation for a serious case of this condition. The patient was a young man, twenty-three years of age, who came to him with a firm enlargement of the tonsil. After an attack of pneumonia an abscess had formed in this tonsil which had to be incised several times. The scar of these incisions had left distinct indurations. Though only the tonsil was apparently involved within the mouth, the external lymphatics of the neck were noticeably enlarged. An intra-oral operation was out of the question, so an incision was made all along the sternocleido muscle almost to the clavicle. All enlarged glands were removed. A ligature was passed around the common carotid about an inch below its division, to be tied if subsequent bleeding should be severe. It was found necessary to tie this ligature before all of the growth could be removed. The patient sank so much after this that the conclusion of the operation was delayed. The wound was packed and the patient responded well to stimulation. The operation was completed very thor-

oughly, all diseased tissue being removed so far as it could be recognized. After five months, however, recurrence took place and the patient died.

Double Carotid Ligature.—Dr. Dawbarn of New York said that he has paid special attention for some eight years to inoperable malignant growths in the pharynx and larynx. The most successful treatment seems to be the extirpation of both external carotids with all their branches. About forty of these operations have been done by Dr. Dawbarn himself and some dozen other surgeons. They give the best results and are not as dangerous as might be expected. It seems that the profession should try this method of treatment in these cases, which are now so commonly looked upon as inevitably fatal.

Dr. Jacobson of Syracuse said that if taken early it is sometimes possible to cure these patients by simple removal with the cautery. He reported the case of a patient thus treated twelve years ago in which there has been no recurrence.

Pelvic Suppuration.—Dr. Chas. P. Noble of Philadelphia presented the results of his various methods of treatment of pelvic suppuration during the last fourteen years. In all there were 200 patients having suppurative conditions. Of these 146 were operated on by abdominal incision. Of the remaining 64 most were operated on by vaginal incision with drainage. This last method has given much better results than any former methods of treatment. The mortality in the treatment of pelvic suppuration was over 16 per cent. before 1895; since that year the mortality has been only slightly more than 6 per cent. and only 4 per cent. if to the operative cases are added those of simple drainage for pelvic suppuration. Other disadvantages besides the cardinal one of greater mortality have also been obviated. Hernia in those operated upon by the abdominal method occurred in over 10 per cent. of all cases. Now it occurs in less than 1 per cent. of all cases. The modern technic of using absorbable catgut instead of silk does away with the danger of subsequent fistulæ, so annoying a sequela in the old days. The vaginal method also removes almost completely the danger of subsequent adhesions from which patients suffered so much and for the relief of which even serious secondary operations had to be performed.

Abandon Radical Abdominal Operation.—Dr. Noble is of the opinion that the radical operation upon the uterus and adnexa through an abdominal incision should be abandoned. Its mortality is apt to be high. If drainage is employed hernia is practically inevitable and adhesions are almost sure to occur, later to be a source of danger and discomfort. On the other hand, by the vaginal route these disadvantages are minimized. In puerperal cases lives are saved and even the ovaries may be preserved for subsequent function, though they would surely be sacrificed by abdominal operation. If by chance the abdomen should be opened and a purulent condition unexpectedly found the vaginal route should be used, the assistant closing up the abdominal incision.

Drainage in Abdominal Operations.—Drainage should not be used in abdominal operations unless it is feared that a hollow viscus has been injured. Even if a pus sac should be ruptured within the abdominal cavity drainage is inadvisable. The peritoneum can take care of infectious material better without drainage than with it. The continuous irritation of a leaking intestine, ureter or bladder, however, soon overcomes the normal resistive vitality. It might seem that simple drainage for pelvic suppuration is a reversion to the old days when simple evacuation of the pus was the only purpose attempted. As a matter of fact the present drainage represents a distinct advance. Instead of the halting-in-the-dark methods of the early days of gynecology, surgeons now know exactly the indications and realize how far they may go with the hope of ultimate success. In the old days patients were relieved for the time being, but very seldom entirely cured. With the modern drainage it is almost the exception not to have permanent relief. The majority of patients do not need any subsequent operative treatment and have very little discomfort. The drainage operation is truly conservative. It saves not only life, but organs. Ovaries are not sacrificed and often retain their function. Dr. Noble has seen six pregnancies occur in cases in which, according to old methods radical removal of organ would surely have been the indication.

True Conservative Gynecology.—Dr. McDonald of Albany said that there was little to discuss in Dr. Noble's paper, because there was little to criticize or disagree with. Undoubtedly the vaginal route has proved an eminently conservative method. False conservatism may, however, asesrt itself to the patient's detriment. When pus tubes are present, for instance, and are to be removed hysterectomy should be done also. Dr. McDonald has seen cases in which neglect of this precaution has necessitated secondary operation. This is not the sacrifice of a healthy organ, for usually the seeds of infection are also in the uterus, though they may not be manifest.

The Sideroscope.—Dr. Thos. R. Pooley of New York read a paper describing the development of this instrument from his original invention. He found by experiments with a suspended magnetized cambric needle that when an iron or steel body was in an excised eye the fact was disclosed by perturbations of the needle. Further experimentation showed that if the iron or steel particle were magnetized or were situated close to the surface of the eye, these perturbations of the needle were sufficiently distinct to be of assured diagnostic significance. He then had a needle constructed with an eye in the middle by which it might be delicately balanced on a thread and used it on certain cases with good results. The principle is that if a foreign body is attracted by a magnet and made to move, if sufficiently light, so also the magnet may be made to move if the body it influences be large enough.

Foreign Adoption of the Sideroscope.—Prof. Pagenstecher of Wiesbaden, the distinguished German ophthalmologist, used the sideroscope with good results which he has reported in the "Annals of Ophthalmology." Pagenstecher succeeded in magnetizing iron and steel particles within the eye by bringing close to it a powerful magnet. This manipulation adds to the serviceableness of the sideroscope. Dr. Asmus, formerly of Breslau, but now of Düsseldorf, has added a scale to the sideroscope and a telescope to facilitate the reading of even minute variations of the needle. Prof. Hirschberg of Berlin has added a small reflecting mirror to the instrument and by so doing has avoided the need for a telescope. The movement of the beam of light so magnifies the slightest variation of the needle that it becomes easily visible.

Gonorrhea of the Prostate.—Dr. John Van der Poel of New York said that the diagnosis of gonorrhea of the prostate is not difficult if care be taken in the method of examination. The ordinary two-glass test, with about equal quantities of urine passed in each glass, is not a certain way. Most of the urine should be passed in the first glass and only a few teaspoonfuls in the second. If this sample of urine be cloudy, there is no doubt that the prostatic urethra and the prostate itself are affected. Gonorrhea of the prostate

is much more common than is thought. The notion prevailed formerly that practically all posterior urethrites affected the prostate. This was much nearer the actual truth than the present set of ideas as to its comparative rarity. The diganosis of gonorrhea of any porton of the urethra from the subjective and objective symptoms is always a mistake. Only the microscope can give assurance in the matter.

Treatment of Prostatic Gonorrhea.—The best method of treatment is with the organic salts of silver. Protargol is a good type. It is extremely soluble yet contains 8 per cent. of the metallic silver. A fresh solution of the drug should be made about every forty-eight hours. First the patient should urinate. This is the natural irrigation and cleansing of the urethra. Then the meatus should be sopped out with cotton dipped in a 1 per cent. solution of protargol. In acute cases, before any manipulations are begun, a solution of cocaine, ½ to ¾ per cent., should be allowed to remain in the urethra for about five minutes. This allays the iritability of the mucous membrane over the cut-off muscle and admits of the injection being made without the induction of spasm. From 250 to 400 grams of a 1-per-cent. protargol solution should then be allowed to flow into the bladder. At times an uncomfortable sense of fulness will occur when about 150 grams have been injected, but, as a rule this is due to the patient's uneasiness bringing on the reflex, and it can be overcome by patiently continuing the injection. The presence of fever or of any tendency to pus-formation constitutes an absolute contraindication to this method. If inevitable, the formation of pus should be encouraged and then it should be evacuated.

Fractures of the Nose.—Dr. John O. Roe of Rochester said that fractures of the nose are not difficult to treat if they are seen before the swelling and inflammatory exudation have made the tissues less tractable. Dr. Roe always employs a nose plate made of aluminum or copper. This can be bent to fit the particular nose and is made of good size, so as to cover the organ completely. A piece of adhesive plaster the size of the nose is applied first to act as a splint and prevent any irritation by the metal. If there is deformity within the nose it is corrected by means of a small sound intended for the purpose. If the physician is without the sound and the nostril is roomy, the little finger can be used to overcome the deformity. To insure against recurrence in obstinate cases Dr. Roe uses a bent spring, the arms of which are covered with rubber tubing to prevent irritation. In severe case the nose should be packed for three or four days until sufficient union has taken place to prevent recurrence of the deformity. To prevent irritation of the nasal mucous membrane, it should be sprayed with cocaine before the nostril is plugged. Dr. Roe exhibited a simple gauze packer that enables the surgeon to place the cotton in any part of the nose.

Importance of Preventing Nasal Deformities.—Dr. Wendell C. Phillips of New York said that entirely too little account is taken as a rule of accidents to the nose in childhood. If the patient does not complain of much pain and if there is but slight external deformity, these cases are often left entirely untreated. The nose is an extremely important organ that serves more than a cosmetic purpose. It is also an extremely delicate organ and even slight external injuries may seriously impair its functions. At times when these patients come to the physician the broken parts have to be refractured in order to be set. It is very easy to treat them if they come before inflammatory changes have taken place. Ball-players especially are liable to suffer from nasal injuries, and it is imperative to keep in mind constantly the importance of early treatment. Otherwise serious pathological changes take place and important functions are subverted.

Deafness and Constitutional Treatment.—Dr. Sargent F. Snow of Syracuse said that for chronic deafness constitutional treatment is even more important than the local treatment of the catarrh that usually forms the basis of the deafness. This fact is often forgotten. While the employment of jets of vapor into the middle ear gives temporary relief, no system of treatment does any lasting good that does not take account of the patient's general condition. So long as the large area of mucous membrane in the intestine, for instance, is not in normal condition, it cannot be hoped that any medication will keep the upper parts of the mucous membrane in nose and pharynx in good condition. With a sluggish liver the secretions of the upper air-passages will be sympathetically disturbed. While the skin is sluggish there can be no hope of properly regulating the mucous membranes. The most important indication is to tone up the general system. For this exercise may be the most important requisite. In older patients it usually is a *sine qua non* of successful treatment. Often the exercises and the practice of deep breathing will be sufficient to create the necessary diversion of circulation that is so stimulant to mucous membranes. Cold baths should be taken for the restoration of activity to the peripheral circulation. If for any reason they are contraindicated, then at least brisk brushing with a coarse towel should be practised. Often the sluggish patients in whom chronic catarrh finds favorite victims are inclined to the habit of warm bathing. This should be discouraged because of its relaxing effect.

Nasal Cleansing.—Dr. Abraham Jacobi of New York said that not only should the other mucous membranes and the skin be kept clean, but all the mucous membranes of the throat and nose should be frequently cleansed. Children should be taught to do this as they are taught to brush their teeth or even to wash their hands. Once a day is not too often for this purpose. For nasal irrigation warm salt solution should be used. In the treatment of chronic catarrhal conditions the use of the absorbent remedies, the iodides, are especially indicated. The iodide of iron is the most important of these for children.

New Charities Bill.—Dr. Edward Fischer of New York then offered a resolution asking the Society to deprecate the passage of the new Lunacy Bill which threatens to undo the progress that has been made in the asylums in this country by taking powers from the heads of institutions to give them to the State Lunacy Commission. On motion this resolution was carried unanimously and the sense of the Society ordered to be conveyed to the committee in charge of the bill.

Suggestion in Nervous Therapy.—Dr. Edward B. Angell of Rochester said that while abroad he had seen tabes treated by Fraenkel's method, by extension and warm baths, by suggestion, and by hydrotherapy. Under all of these methods it improved. Evidently the patient's state of anticipation has much to do with the improvement. Physicians must learn to use more and more deliberately this great therapeutic force of suggestion. It is even more important for the neuroses than for the serious nervous diseases. For the hysterical this must consist in the substitution of the physician's will for that of the patient. Every hour of the day should be mapped out for them; "charted" is the expression of S. Weir Mitchell, who made some of his greatest successes in this way.

Endotheliomata of the Ovary.—Dr. Mary Dixon Jones of New York described certain peculiar tumors

of the ovary pronounced malignant by distinguished authorities in pathology, but without the clinical aspects of malignancy. If they were malignant they would cause dreadful mortality, for they are very common. These tumors are probably endotheliomata. At times they have the general character of hematomata. Not infrequently they resemble epitheliomata, not only in their general character, but even in their microscopic details.

New Bisection of Uterus.—Dr. C. H. Richardson of Albany described a new method of cutting the uterus in two for removal by the vaginal route. When hysterectomy is to be done it is usually because the uterus has been infected and it is undesirable for its contents to reach the operation wounds. All sections that open the cavity of the uterus submit the patient to this additional risk. Dr. Richardson suggests the incision be made not in the median line of the uterus, but to either side through the muscular tissue of the uterus. By a little care, in this way, the cavity of the uterus remains intact and all danger of infection from this source is rendered nil. Dr. Richardson has employed this method with good results. He does not extend the incision so as to pass through the cervix, for this exposes the vagina to infection.

Backwoods Typhoid.—Dr. E. G. Brush described an epidemic of typhoid that occurred in the Maine woods. The first case was that of a boy who contracted the disease either by bathing in a river sixty miles below where there had been some cases of typhoid fever in a lumber camp several months before, or by association with lumbermen who were carrying the bacteria of the typhoid with them, though it did not develop for some time later. All the subsequent cases can be traced to this one. The families lived far apart, but during sickness, in order to be of help, they visited houses in which the disease existed and carried it home with them. In one family in which six members of the family developed the disease, the source of infection seemed to be the water barrel. All were accustomed to drink out of the barrel with a common dipper and to throw back for subsequent use whatever water was left. In other cases the fecal distribution of the disease could be easily traced. In this one family, however, there was no opportunity for it and the distribution seems to have been from mouth to mouth.

Strangulated Ovarian Hernia.—Dr. Bristow of Brooklyn described an operation for this rare condition. The patient at eight years of age was kicked, though not severely, by a horse. A tumor developed in the inguinal region which was reducible. After several years it disappeared and was not noticed again until the patient was forty years of age. Then the hernia redeveloped while the patient was lifting a heavy weight. Shortly before coming for treatment the hernia apparently came down one day, but could not be reduced. The tumor was very tender and gave great discomfort. It did not give the characteristic symptoms of strangulated hernia, though there was some nausea. On operation the tumor was found to contain a tube and ovary. These were replaced and the patient made a good recovery.

Ovarian Hernia in Children.—Dr. Bristow said the ovarian hernia is much more common in children than in adults. The reason is said to be that the ovaries are placed much higher up in early life than at a later period.

Inguinal Canal of Children.—Dr. Abraham Jacobi said that the inguinal canal in children is much shorter than in the adult. Moreover it is almost straight. The internal and external ring are almost on the same plane. This fact, with the extreme delicacy of infantile tissues, accounts for the greater frequency of hernia in children. This explains also the tendency of other organs besides the intestines to find their way into infantile hernial sacs.

Large Dosage in Nervous Diseases.—Dr. Wm. C. Krauss of Buffalo said that one great reason for the impotence of therapeutics in nervous disease is that insufficient doses of drugs are employed. In syphilis of the brain, for instance, he believes that enormous doses of mercury should be employed. He uses the corrosive sublimate by the injection method and in cases of necessity does not hesitate to use even as much as a grain at a dose. Of course a certain tolerance to the drug must be obtained by gradually increasing doses or fulminant toxic symptoms would develop. Dr. Krauss prefers to give mercury by injection, as the ptyalism and other symptoms of its administration are less. Fowler's solution is of the greatest service in chorea, but the small doses administered utterly fail to enable it to exert properly its activity. The dose is said to be 1 to 10 minims, with a maximum of 15 minims allowed by some. Dr. Krauss gradually increases the dose of Fowler's until the patient is taking 30 minims or sometimes even a spoonful of it. This gives effects when the small doses utterly fail. For neuralgia Dr. Krauss believes in pushing nitroglycerin. He has had a patient take as much as 30 minims of a 10-per-cent. solution of nitroglycerin and another patient, taking the drug for a year, was able to take a teaspoonful of a 10-per-cent. solution without inconvenience and with good therapeutic results.

Generous Dosage for Therapeutic Effect.—Dr. Abraham Jacobi of New York objected to the title of Dr. Krauss's paper, "Toxic Dosage in the Treatment of Some Nervous Diseases." He said that the word "toxic" would deter general practitioners from taking advantage of the practical suggestions the paper contains. With many remedies it is necessary to use them to distinct physiological effect or no therapeutic result will be obtained. Alonzo Clark showed fifty years ago that opium, to have its curative effect, must be used to what would ordinarily be thought excess. Dr. Jacobi himself uses ten to twelve grains of digitalis repeated three or four times at intervals of three hours, so that thirty to forty grains are given within eight or ten hours. These doses are not employed in ordinary cases, but when special indications call for special measures. In pneumonia, when oxygen fails to give relief and the right heart is failing, this heroic treatment has often saved life.

Alcohol in Pneumonia.—Dr. R. H. M. Dawbarn of New York said that Dr. E. G. Janeway of New York told of his personal experience in double pneumonia. He was under the care of the elder Loomis, who insisted at the critical period of the illness in administering two quarts of brandy each day for two days. Dr. Janeway ascribes to this heroic stimulation his recovery from the extremely severe symptoms under which he was already laboring when this free administration of the brandy was begun.

Large Dosage in Delirium Tremens.—Dr. Hopkins of Buffalo said that in hospital experience major delirium tremens is an extremely serious disease. Very few of the cases recover. Of late he has found that the use of heroic measures may be successful in averting the fatal issue. He does vivisection and according to the size and appearance of the patient takes away from sixteen to thirty-two ounces of blood. This is replaced by the subcutaneous injection of an equal amount of normal salt solution. Since using this method of treatment the mortality of these cases so

often fatal before has been reduced to below 2 per cent. The venesection removes a good deal of the poison from the system. The use of salt solution prevents the circulation from laboring with blood too thick and, moreover, it encourages the emunctories, especially the kidneys and the skin, to further elimination of toxic substances.

Large Amounts of Digitalis.—Dr. Lyons of Geneva said that he has had something of Dr. Jacobi's experience with the life-saving properties of large doses of digitalis. In a case of major delirium with very threatening symptoms and in which it seemed that the heart must surely fail, he stayed by the bedside during the night and administered teaspoonful-doses of the tincture of digitalis every hour for six hours, so that the patient received all together four ounces of the remedy. The action was most favorable and the digitalis seemed to be life-saving in effect.

Carotid Extirpation for Malignant Growths.—Dr. A. T. Bristow of Brooklyn said that he has had clinical and surgical experience with three cases of inoperable tumors, malignant in character, in the neighborhood of the throat in which he tied the carotids in the hope of starving out the malignant neoplasms. In a recent case he tied off the external carotid itself and all of its branches except the submaxillary. This he occluded, in the manner suggested by Dr. Wyeth, by the injection of gelatin. No bad results followed and the tumor at once began to decrease in size and has given the patient very little discomfort since. In an ordinary thin person there is very little difficulty in reaching and tying off the arteries. In Dr. Bristow's last case, however, his patient was a stout man with a short neck and the difficulties were extreme. The arteries were deep in the tissues and hard to get at. The bifurcation of the common carotid was much higher than usual and the search for the branches very elusive. Only with great difficulty and very little satisfaction was the operation finally accomplished.

Pathology of X-Ray Changes.—Dr. Carl Beck of New York City said that the changes in the skin and deeper tissues caused by the X-rays are well known. The terra-cotta-like hands of X-ray experts and the cracked and fissured hands with altered nails of those who work much with the agent are well known. Now the X-rays promise to be curative as well as harmful. In cancer and lupus they have undoubtedly done good and produced lasting benefit. The principal change produced is in the arteries. Inflammatory conditions in and around these lead to limitation in the caliber of the arteries and this at least partly shuts off the blood-supply to the skin and other tissues. In this way malignant growths are starved and low-grade pathological tissue, such as occurs in lupus, is destroyed. Such tissue has less resistive vitality and less reactive force than normal tissue. Dr. Beck reported some cases of lupus in which the X-rays have accomplished good results after many other forms of treatment had failed completely. This new therapeutic agent is of great promise and seems but the prelude to other similar remedies.

Civilized Indians.—Dr. H. D. Lake of Gowanda described the changed conditions of life of the Iroquois Indians and the consequent deterioration of health. They were magnificent specimens of manhood and womanhood when the Whites first came. Now they have taken on tendencies to obesity and have decreased in average height. They have lost their great strength and their capacity to stand fatigue, cold and hardships. Especially have they taken up the vices of civilization and suffered from its diseases. Alcohol has caused them to degenerate rapidly and has lowered their resistive vitality for disease. Tuberculosis has especially proved fatal to them. Only for their wonderful fertility this would have wiped them out long ago. Pneumonia is seldom recovered from, or, if it is, it is followed by acute or chronic tuberculosis. Bronchitis is very frequent and is liable to have tuberculosis grafted on it. A young man comes for the treatment of some apparently mild disease and proves to have serious ravages of tuberculosis in his lungs.

Venereal Diseases.—An epidemic of syphilis among these Indians lasted ten or fifteen years. Now the Indians seem to be immune. It is rare to see an initial lesion among them. The scars of the disease may be seen in the older men. They were treated by their medicine men with herbs and no mercury was used. No case seems to have gotten well in less than two years. Syphilis has undoubtedly added to the degeneration of the tribe. Gonorrhea now rages among them and the women suffer severely from the effects upon their internal sexual organs. The Indians have suffered by getting away from Nature. A marked improvement has come among them in recent years as the result of the school-training of the younger generation. They have been trained by athletic sports in the midst of their college work and come back as magnificent specimens of humanity to retain their good habits and be a source of emulation to others.

The Smallpox Problem.—Dr. Ernest Wende of Buffalo said that the present widespread epidemic of smallpox brings up very opportunely the question of the necessity for special training for medical officers of health. Undoubtedly the spread of the disease throughout the country has been due at least in part to failure of authorities to recognize the disease immediately on its introduction into a new neighborhood and this has allowed the disease to gain a foothold. There is need in this country of a special set of post-graduate courses for the instruction of health officers in those duties that require immediate action or there may be serious results. The present system that allows health officials to be a part of the patronage of a political boss, so that favoritism and not capacity for the position counts, is fatal to true hygiene. If fully and properly applied vaccination would suffice to stamp out smallpox in this country. Unfortunately, there is a class of even educated people who unite in opposition to vaccination. Vaccination regulations must be enforced and the danger from smallpox will be diminished. There is any amount of recent statistics in foreign countries to prove the protective influence of vaccination. Efforts spent on enforcing this idea are not lost, because they apply not only to smallpox here and now, but they make clearer to people the usefulness of preventive medicine in other diseases.

Vaccination as an Extinguisher.—Dr. Smith of Cohoes said that vaccination puts out smallpox as a pitcher of water puts out a small fire at its inception. It is just as criminal to permit smallpox to gain a foothold in a community for lack of vaccination as it is to let a conflagration grow out of a little fire for lack of water.

SYMPOSIUM ON PARESIS.

Etiology of Paresis.—Dr. Arthur W. Hurd of Buffalo said that recent statistics serve to show that syphilis is probably the principal cause of paresis. Foreign statistics give a higher number of paretics who have had syphilis than do statistics collected in this country, but that militates very little against the theory of the syphilitic origin of the disease if certain considerations are kept in mind. In this country friends are more apt to be ignorant of the syphilitic incident in the patient's history, or, if they do know it, they are from motives of delicacy more prone to con-

ceal the fact than is the case in foreign countries. The average number of paretics who are also syphilitics is about 68 per cent. This is all the more striking as less than 10 per cent. of other forms of insanity have a syphilitic history. It has been found in London that of the patients who had undoubted skin lesions of syphilis, only 80 per cent. confessed to having had the disease. They were either sincerely ignorant or they deliberately tried to deceive. Many of the skin lesions were comparatively recent, so that the history was fresher in mind. In Vienna out of over 80 patients suffering from indubitable tertiary symptoms of syphilis, only 54 per cent. gave a history of an initial sore and secondary symptoms. This set of statistics represents almost the same number of exceptions that occur among paretic patients. The fact that some paretics apparently have no syphilitic history does not argue very forcibly against the syphilitic origin of the disease in by far the majority of the cases.

Experimental Inoculation.—In Europe experimental inoculations that would be considered unjustifiable in this country were made with the virus from syphilitic patients upon asylum paretics. Altogether nine hopelessly demented paretics were thus inoculated. Not one of them took the disease—a sure sign that they must all have had syphilis before and acquired immunity to it. Most of these paretics were patients who gave no history of syphilis and in whom, therefore, the existence of immunity might be doubted.

Paresis Distribution.—While Egypt and Japan suffer very much from syphilis, paresis is rare in either country. This is evidently due to the fact that some other causative element besides syphilis is needed. Syphilis provides the basis for the development of paresis, but nervous overwork, emotional strain, at times even physical exhaustion, furnish the additional causes. Egypt is noted for the do-nothing character of its inhabitants and Japan has not as yet been touched enough by the excitement of the new Western civilization to get into the condition of hurry and worry that actively predisposes to paresis. As Krafft-Ebing said, the two causative elements are syphilization and civilization. The latter factor as yet spares Egypt and Japan. Paresis is most common among military men, actors, good livers, brokers and professional men liable to lives of nervous strain. It is very rare among clergymen, Quakers and among country-people generally, while very common in the large cities. The disease is much more rare among women than men and, in women of the different classes of society affects most those who are most liable to be affected by syphilis. Very few women of the better classes suffer from it.

Juvenile Paresis.—The disease used to be considered very rare in children and youths, but certain special forms of it have been found to occur quite frequently of late years under the age of twenty. In most of these cases there is a history of hereditary syphilis. In some of them there is a history of acquired syphilis. While ordinarily the sexes are very unequally affected, the proportion being usually at least four men to one woman, in these juvenile paretic cases the proportion in the two sexes is nearly equal, as would be expected, since heredity acts impartially to both sexes.

Previous Degenerative Condition.—It has often been noted that, in patients in whom paresis developed after syphilis, symptoms of some mental weakness had existed before the syphilitic infection. It would seem that syphilis finds in an invalid brain an especially favorable field in which to produce further degeneration. Even after syphilis not everyone becomes paretic, but only those whose nervous systems were not over stable beforehand. The changes, for instance, produced by alcohol in the nerve tissues may predispose to paretic changes after the acquirement of syphilis. Trauma or sudden emotion may act on a syphilitically-predisposed nervous system to produce paresis. There can be no denial of the fact that these other conditions are contributing causes of no little importance. It is hard to know just the rôle that alcohol plays in these cases since devotees of Venus are also as a rule worshippers at the shrine of Bacchus and *vice versa*.

Ripening Elements in Etiology.—Certain pathological conditions seem to mature the tissues for paresis after syphilis has done its work. Trauma is one of these. The cases, however, in which trauma has played a causative rôle apart from syphilis are so rare as to be doubted by most authorities. Syphilis, while not the sole factor, is certainly the most frequent cause of paresis. It cannot be found as frequently in the history of paresis as in tabes, but this is rather confirmatory than otherwise, since tabes and paresis are very similar pathological conditions.

Early Diagnosis of Paresis.—Dr. Francis Dercum of Philadelphia said that the problem of the early diagnosis of paresis is not easy. Mistakes are frequent. It is not unusual to find that paresis has been treated for months as neurasthenia when eventually recognized. The resemblance is only superficial, however, and should not deceive the trained and watchful observer. Both classes of patients may complain of being tired, of having peculiar feelings and general symptoms, but the complaints come in very different ways. Of course, when the loss of muscular tone that gives the slouchy walk and blankens the facial expression have developed, it is not hard to recognize paresis, but the disease has certain pathognomonic characteristics long before this.

The Neurasthenic: the Paretic.—The paretic patient seldom comes of himself to consult a physician. He is brought by his friends. He, unlike the neurasthenic, has no long story to tell. Symptoms will be found, but only on careful questioning. He has ringing in the ears, *muscæ volitantes* or sparks before the eyes, and he may have severe lightning-like pains. His friends will tell of lapses of memory and inability to care for his business. As a rule the paretic is scarcely conscious of these things himself. The friends are alarmed about his condition. The neurasthenic, on the other hand, complains of loss of memory and tells of every pain and ache and of every slightest sensation that can be translated into pains or aches for weeks before his visit. The neurasthenic's pains are vague. His friends rather laugh at his symptoms.

Sleep in Neurasthenia and Paresis.—The neurasthenic sleeps well at the beginning of the night; then wakes to remain fretfully awake and rises in the morning tired, not caring to face the day. Toward evening the neurasthenic feels best and is almost ready to persuade himself that there is nothing the matter with him. The paretic tosses during the night and sleeps a little toward morning. He wakes rather refreshed from his sleep and feels best in the morning. Toward evening he becomes exhausted and all his symptoms are then at their worst.

Neurasthenoid Stage of Paresis.—Dr. Dercum thinks it eminently undesirable to say that the first stage of paresis is neurasthenia. The symptoms recall neurasthenia and resemble them somewhat, but can be rather easily differentiated. The visual fields are distinctly narrowed early in paresis and this is a pathognomonic sign. Only very severe cases of neurasthenia have the symptom and then it varies from day to day. The paretic by his manner at once reveals that he is out of touch with his environment. There is a vacant expression even before the smoothing out of the facial furrows from loss of tone in the facial muscles has

taken place. There is a vacant distrait air even before mental symptoms have become very prominent. The preparetic manner is an entity that really exists and is readily recognizable by those who have had considerable experience with it.

Frequency of Paresis.—Dr. Charles G. Wagner of Binghamton said that paresis was first definitely recognized only about eighty years ago. Esquirol described some cases before that which were probably paretic, but he did not realize the significance of the symptom-complex. The disease was not recognized in America until much later. It was very rare in this country even in 1840. It was not overlooked, for some specialists in mental diseases who had seen it abroad were on the watch for it. Statistics show that there has been a constant increase of the disease ever since 1850. During the decade between 1850 and 1860 it first began to play a prominent rôle in the insane asylums of this country.

Present Incidence of the Disease.—At present somewhat less than 10 per cent. on an average of the patients in American insane asylums are suffering from the disease. This is much less than abroad. In foreign asylums between 20 and 30 per cent. of the inmates are paretics, with most of the statistics nearer 30 per cent. than the smaller number. There is quite a little variation in the numbers suffering from the disease from year to year. About the middle of the last decade the figures were higher than at present.

Paresis in the Professions.—At one prominent asylum in this country the professional men suffering from paresis are divided as follows: Actors, 8; lawyers, 7; doctors, 5; military men, 4; clergymen, none. These represent about the usual proportions. Clergymen are usually spared and this is undoubtedly due to the fact that they have syphilis less frequently than members of any of the other professions. The disease attacks those who have trying work to do, who live on their nerves, and spend life in the midst of emotions. The overworked doctor suffers more from mental strain than from physical fatigue.

Other Occupations.—Other trades are not spared. The butcher, the baker, the candlestickmaker, the merchant, the shoemaker, all count a goodly number among the inmates of asylums suffering from this dreadful disease. It is sometimes said to attack head-workers in preference to handworkers, the educated rather than the uncultured. The reports of American asylums at least do not bear out this statement. It is worry, not work that predisposes the syphilitic, or the alcoholic, or the otherwise degenerate to the paresis about to develop. The statistics of our asylums show that the disease rages especially among the native-born. There is a great preponderance of native Americans among the paretic inmates, though, taking the patients at asylums altogether, about two-thirds of them are foreign born.

Deaths from Paresis.—Most of the deaths take place between thirty and forty-five, though asylum reports show deaths under twenty and even over seventy years of age. The disease is inevitably fatal. Dr. Wagner was able to find only one case in recent medical literature in which there was claim of a cure. The disease presents decided remissions and these sometimes last for months. The average duration of the disease, however, is only about two and one-half years. Very seldom will a patient with typical paresis live five years from the first symptom of the disease. The disease is undoubtedly on the increase in this country and careful study will lead to its earlier detection than heretofore.

Limits of Treatment.—Dr. Edward Cowles of Boston said that in the presence of true paresis the physician is absolutely helpless. Very early in the disease when only neurasthenic symptoms are present a history of syphilis confirms our suspicions as to the existence of paresis, but its presence does not help the therapeutics of the disease. Antisyphilitic treatment does no good and probably even does harm once the initial symptoms of paresis have declared themselves. In the early stages of the disease it may, perhaps, be kept from running so rapid a course as it otherwise would by lessening the mental strain on the individual. Oppenheim says paresis is due to stress and syphilis. The stress can be lessened at once with the hope of prolonging the life of the patient. Kraepelin thinks paresis a nutritional disease not unlike myxedema and due to some poison in the blood or the failure to neutralize some toxic product. Sir Dyce Duckworth suggests that paresis is an auto-intoxication. This causes changes in the nervous systems which react to lower tissue metabolism and cause further toxic degeneration of the nervous system. This idea makes the therapeutics in very early stages not quite so hopeless.

Serum Treatment.—Two Scotch observers recently have declared paresis to be due to an intestinal intoxication. Bruce noticed that the initial stage of the disease was always ushered in with gastric disturbance and fever. He procured some serum from blisters of a paretic patient suffering from lumbago during a pronounced intermission in his paresis. This injected into other patients produced an intermission in the others. Bruce proposes to inject horses with colon bacilli and thus produce a serum that he thinks will be of benefit in paresis. Dr. Robinson, the other Scotchman, thinks paresis due to the effect of auto-intoxication upon the cerebral blood-vessels. He considers the toxic substances of intestinal origin and hopes to be able to neutralize their effects before they work their most serious evils.

Second Day—January 29th.

Prize Essays.—The only essay submitted bore the title "A Study of the Connective Tissues of the Orbit by a New Method." This enables the recognition of the capsule of Tenon, the insertions of the muscles, and other parts of the tissues of great practical interest. The essay bore the motto "*Palma non sine pulvere.*" The name of the author is Dr. Lucian Howe of Buffalo, and to him was awarded the prize offered by the Society.

Treasurer's Report.—The annual expenses of the Society exceeded its income by over $800. The two items that explain this deficit are the salary of an additional secretary at $350 per annum and the semi-annual meeting, the expenses of which were about $500. The Committee reports that if the present deficit continue from year to year, it will not be long before the surplus at present in the Treasury will be materially lessened.

Treatment of Ringworm.—Dr. George Thomas Jackson of New York said that ringworm of the non-hairy skin is easy of treatment. Most of the cases do not come for treatment, but are cured by sulphur ointment or some simple home remedy. On the hairy scalp it is very obstinate and the patient wanders from doctor to doctor. Dr. Jackson has for some years been using a remedy that gives excellent results. He employs goose grease as an excipient. A dram of iodine is dissolved in an ounce of the goose-oil. The remedy is applied twice a day until some irritation is produced, then only once a day. If the reaction is severe the remedy is stopped for some days. The pain of the application is a little severe at first, but passes off. The first effect of the remedy is to cause the fall of the hair so that the patch looks like one of alopecia areata.

After a time a new growth of hair occurs and this is the sign of cure. No epilation is needed. The method is extremely simple. If the reaction is severe, salicylated oil may be employed for some time until the inflammatory condition lessens. It takes just three weeks now to cure barber's itch, formerly so obstinate a disease. This is true not only in private practice but also in hospital practice. Certain rare cases resist even this treatment. For these Dr. Jackson recommends one-half to one dram of croton oil to an ounce of sulphur ointment. It is not always easy to get genuine goose-grease. There are factitious articles sold under the name that are unsuitable. A reliable drug-house will furnish it, however.

Three Years' Experience.—Dr. Baum said in the discussion that he had had three years of experience with this method of treatment with such excellent results that he heartily endorses Dr. Jackson's recommendation. On sensitive skins Dr. Baum has found 5 per cent. wintergreen-oil ointment very satisfactory.

Society Initiation and Neurosis.—Dr. Frederick Sefton of Auburn gave the details of a case in which the history included severe hazing. The patient, a student at an academy, in the course of initiation into a secret student society was taken at night to a graveyard and made to sit for half an hour on a tombstone; then he was hung up by the thumbs till he fainted and lastly rolled in a barrel with nails on the sides. During this procedure he lost consciousness and could not be revived, so he was left in the hallway of his home. He did not return to the school. About a year after he began to be peevish and irritable, especially to his friends. Finally, in a state of excitement he attempted to shoot his sister. He was followed, tried to escape, lost consciousness, and when he came to said he had no memory of his acts during the period of excitement.

Psychic Epilepsy.—Later he had several such attacks. In one he was found suffering in the garden and had evidently taken some of the Paris-green he was using for potato bugs. He had no memory of this, but asked not to be left alone any more lest he should hurt himself. Under bromides and outdoor exercise he improved. He has now been for several years the purser of a coastwise steamer and is healthy and happy. All his friends believe he had lost his consciousness when he attempted murder and suicide. It is evident, however, how serious would have been his case had he killed his sister when he shot at her. Dr. Sefton used the case as an illustration of the necessity for an impartial medical expert to advise the Court in such cases.

Fright and Epilepsy.—Dr. William Browning of Brooklyn said that fright can only be considered a cause in epilepsy when it immediately precedes the original attack. These cases are complicated medico-legally by the fact that it is only when patients are irritated by some interference with their plans that they become violent. This adds to the suspicion of guilt.

Pseudoleucemia.—Dr. John L. Heffron of Syracuse said that the pathogenesis of Hodgkin's disease or pseudoleucemia is as yet a mystery. The best authorities seem to think that the disease is a tuberculosis of the lymphatic structures. Hence, the following case may be interesting. The father suffered from gravel and endocarditis. His mother's family history contained heart-disease also. The patient came to be treated for a cough. Enlarged glands were found above the clavicle. The superficial veins were enlarged over the anterior thorax. All the other lymph-glands were enlarged especially on the right side. There was some bagging of the right lung. Some subcrepitant râles on deep inspiration were to be heard. Sputum was collected, but no tubercle bacilli were found. The blood gave a simple picture of anemia. He was advised to use Crédé's ointment and the iodides were used internally. His skin became very itchy. His breathing became more and more difficult, especially when lying down. It was evident that some enlarged glands were pressing on the right bronchus and almost occluding it. He coughed more, but still no tubercle bacilli could be found. His urine was carefully examined for tubercle bacilli, but none were present. He gradually grew worse, orthopnea developed and he died from the pressure of the enlarged glands upon nerves and arteries as well as the bronchi. Careful examination of the tissues was made after death to find if possible tubercle bacilli anywhere in the body. The only condition present was a lymphosarcomatous degeneration of all the affected glands.

Leucocytosis in Diagnosis.—Dr. Thomas R. Brown of Baltimore discussed leucocytosis as an aid to diagnosis and prognosis. He said that Metschnikoff's phagocytic theory brought the white blood-cells into prominence. In more recent years the blood-serum has been found bactericidal and this has seemed to lessen the importance of the white cells for resistive vitality. Since it has been shown that the bactericidal properties of the blood-serum are due to nucleoproteid substances the white cells have regained their reputaton, for these substances are contained in abundance in the white cells. The presence of a physiological leucocytosis during the height of digestion should be a warning not to count the leucocytes for diagnostic purposes just after a meal.

Eosinophilia.—The presence of a large number of white cells that give the eosinophile reaction is of special significance. In typhoid fever it means a favorable prognosis if it occurs early. In trichinosis eosinophilia is almost pathognomonic. It occurs also in cases of intestinal parasites as the anchylostoma duodenale. It is probable that for soldiers returned from the tropics this reaction may serve to rouse suspicion of the presence of intestinal parasites that might otherwise escape notice. Dr. Brown said that an excess of lymphocytes is present in the blood in a very early stage of whooping-cough. This enables the disease to be recognized during the period of simple catarrhal symptoms and precautions may be taken not to expose other children. The differential blood-count promises to be of service in the detection of a number of infectious diseases. This is the most common form. It usually means severe infection or pus formation. In a case of acetanilid-poisoning this form of leucocytosis was present, giving rise to the idea that secret drug habits may perhaps be detected by the blood-count. Sudden rises and falls in the number of leucocytes usually call serious attention to the patient's condition. In appendicitis it may mean perforation with peritonitis. In general, it may be said that blood-counts are not infallible and must not be taken alone, but in connection with other symptoms it is often of diagnostic importance.

Abscess of Liver.—Dr. Edgar A. Vander Veer said that abscesses are usually associated with dysentery. Knowledge of the subject comes from India. Interesting material on the subject is now coming from the Philippines. This case reported was thought to be one of empyema until the dressings were saturated with bile. The patient had served in the Philippines, where he contracted dysentery. As this could not be cured he was finally discharged. For a year his dysentery continued with some intermissions. Finally, he developed a tender swelling on the right side that greatly interfered with respiration. This was thought to be in the pleural cavity. It was aspirated and three and one-half pints of brownish purulent fluid removed.

Later on an open incision was made and 1,000 c.c. of similar fluid drained off. This contained no micro-organisms. It was suspected to be tuberculous or to be due to the pneumococcus, the organism, as sometimes happens in these cases, having disappeared. When the bile flow began the true nature of the case was realized. The patient made a good recovery, though for a time his dysentery became severe again.

Gunshot Wounds of Liver.—Dr. E. W. Mulligan of Rochester detailed the case of an Italian salt-miner who shot himself in the abdomen while in a fit of despondency. Wounds of the liver have heretofore been thought practically always fatal. During the Civil War very few recovered. Pirigoff, in 1865 said they were always fatal. Of the three conditions of the liver, ruptures are most fatal, incisions next, and gunshot wounds least fatal, but even these have a mortality of over 60 per cent. Fortunately, the prognosis is now growing better because of modern advances in surgery. Schlatter advises tamponade of the wounds; the cautery cannot be trusted entirely and sutures tear out. Bergmann suggests protecting sutures with gauze to prevent their tearing through the liver tissue. The wound of entrance into the liver in Dr. Mulligan's case was small and needed no treatment. The wound of exit was jagged and torn, bleeding profusely, and required packing. Three yards of gauze were used for packing and the end brought out through a counter-opening made for drainage. The bullet was found in the muscles of the back and was removed. The patient was out of the hospital in a month after his frustrated suicide.

Surgical Treatment of Peritoneal Tuberculosis.—Dr. John W. Whitbeck of Rochester reported three cases of tuberculosis of the peritoneum treated by incision and irrigation of the peritoneal cavity with salt solution. The first patient had suffered for some time from abdominal tenderness and accumulation of fluid. The abdomen was opened, irrigated with salt solution and the patient made a good recovery, being now healthy and strong. The two other patients died, one from pulmonary tuberculosis, the other from a tuberculous rectal fistula. These latter cases seem not to have been taken in time.

Unusual Herniæ.—Dr. John B. Harvie of Troy said that operators for hernia have found almost every viscus in the sac. Dr. Harvie has found the ovary several times, the appendix a number of times, and even the kidney, a loose floating organ, presented at the hernial ring after reduction of the intestinal contents of the sac. In a recent case he found the urinary bladder in the sac. The viscus was not recognized until after incision, when urine flowed. It was then reduced and a catheter passed every hour. The patient recovered without incident. In a number of reported cases the bladder's presence has been unsuspected and it has been wounded. It needs to be looked for more carefully.

Modern Methods of Diagnosis.—The President, Dr. Henry L. Elsner of Syracuse read his annual address on the subject of "The Value to the Physician of Modern Methods of Diagnosis." [See page 193.] He said that in recent times advances in the application of scientific principles to the diagnosis of disease have brought with them a metamorphosis of the art of medicine into a practical science. The laboratory is now recognized as the right hand of the medical man. Physicians who have failed to keep in touch with laboratory diagnostic methods are now far behind their wiser fellows. The sale of such books as that of Von Jaksch or that of Simon shows how widespread is interest in scientific diagnosis. The president then spoke of the advances in the chemical diagnosis of gastric disease, of the microscope and the centrifuge in urinary diseases and of the progress in the diagnosis of hematological conditions. All these are in the line of securing greater exactness of diagnosis. The old objection that a man cannot be scientific and a good practitioner no longer holds. The hope of the future of medicine is the union of scientific training with clinical training. For this the Twentieth Century opens most auspiciously.

Election of Officers.—The following officers were elected for the coming year: President, Henry Reed Hopkins, Buffalo; Vice-President, William A. Moore, Binghamton; Secretary, Frederick C. Curtis, Albany; Treasurer, O. D. Ball, Albany.

[*To be continued.*]

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held December 3, 1901.

The President, Joseph Collins, M.D., in the Chair.

Tumor of Brain.—Dr. M. Allen Starr presented a woman who had been brought to him by her family physician, Dr. Bush, on November 1, 1900. She had been perfectly healthy before this illness and there was absolutely no history of specific disease. On July 1, 1900, she had been exposed to a very intense heat and suddenly after this she had had a general convulsion. She had been ill after this for two or three days and had then recovered, but the convulsion had been repeated two weeks later and she had had them at intervals of two weeks to a month up to the time of coming to him. During this period she had lost flesh and strength and had suffered from dizziness and impairment of vision. In October, 1900, the left side of the body had become distinctly weaker. Her husband was quite positive that the convulsions were usually limited to, or were much greater on, the left side of the body. The attack began with numbness in the finger and thumb of the left hand; then a closure of the hand occurred, after which the numbness extended up the forearm and arm, and the forearm became flexed and the arm abducted. Lastly, there was a shaking. The numbness would extend up to the shoulder and then she would lose consciousness. After that the leg would become convulsed and the left side of the face would twitch. On examination he had found no strabismus or apparent paralysis of the face or tongue. The left hand was weaker than the right, as shown by the dynamometer. The left knee-jerk was increased, and there was some numbness in the hand as compared with the other side. She had suffered a good deal from headache. When seen a month later the attacks were more frequent, so that she was having as many as eight in a day, and the headaches were more severe. When seen again in January, the attacks still continued, but were not quite so severe, and she did not lose consciousness. She was losing about half a pound of flesh a week. The difference in the two hands by the dynamometer was represented by 40 and 60, as they had been at first. Operation had been repeatedly urged by him, but consent had not been obtained until March 19, 1901, when her condition had been much poorer, and there was a beginning optic neuritis. She had been sent to Dr. A. J. McCosh at the Presbyterian Hospital. It was thought that the lesion was located in the middle third of the motor zone, in the posterior central convolution, and an incision was made in accordance with this view. The operation was done under chloroform, a horseshoe incision being used. The skull was sawn through and the brain exposed. On lifting up the flap of bone, it was evident that there was some thickening of the

dura. The dura was reflected, but was nowhere found to be adherent. Posterior to the fissure of Rolando and occupying the middle third of the posterior central convolution, the brain surface was yellow and was markedly destitute of blood-vessels. It was evident that this discolored mass was a tumor lying upon the brain. It had a thin capsule, but was carefully separated from the brain tissue. In the interior, however, it was not limited by a capsule. On removal, the mass measured one inch anteroposteriorly and 1¼ inches vertically, and was one inch thick at its thickest point. There was a smooth external surface, but it was nodular internally. On section, it was hard and not at all vascular. The cavity in which the tumor had lain was lined by compressed convolutions, but at the bottom the tumor invaded the white matter. There was no hemorrhage from the pia and the pulsation of the brain quickly returned. She made a rapid and uninterrupted recovery from the operation. Immediately after the operation there had developed a hemiplegia of the left face, arm and leg. This had gradually passed off and there was nothing left of it except a slight weakness of the hand. She had been entirely free from the attacks since the operation, had been free from headache and had gained about twenty pounds in weight. At the present time there was an intention tremor and an athetoid movement in the left hand. On the left side tactile sensation, temperature, pain and muscular sense were all impaired to about the same extent. She was not able to determine by the feeling the nature of many objects when grasped by the left hand—a condition that had not existed before the operation. The knee-jerk had increased upon the left side. The optic neuritis had entirely disappeared. The hemiplegia he would ascribe to the tearing of the brain during the operation. The tumor proved to be a sarcoma.

Intense Flushing of the Face.—Dr. Edward D. Fisher presented a man of twenty-two, who from the age of sixteen had had periodic attacks of intense flushing of the face, sometimes in the form of a distinct red band. It never extends farther down than the chest. He is dull and stupid at these times, although he has never lost consciousness or had a distinct epileptic attack. It was not connected with nervousness or emotions; it resembled erythromelalgia. Iodide and bromide of potassium were the remedies that had given the greatest relief. The man's habits were excellent, and he is largely in the open air, being a carpenter.

Dr. W. M. Leszynsky said that he had seen two patients with a similar disturbance of the cervical sympathetic as a result of excessive coffee drinking.

Dr. Joseph Collins suggested that the man be given half a dram of fluid-extract of cascara sagrada every night for two weeks, with no other treatment whatever. The affection was evidently a localized vasomotor paresis confined to the cephalic area which had been proved to be in connection with disturbance of the lower intestine. He was not inclined to look upon this as a serious disorder, but rather as originally a toxemia and secondarily a bad habit.

Dr. Joseph Fraenkel said that he had had a similar case under observation for several weeks at one time, and Dr. C. L. Dana, who had also seen the patient, had been of the opinion that it was a vasomotor paresis arising from intestinal toxemia. There were also some neurasthenic symptoms directed to the sexual sphere.

Dr. Fisher said that he had treated the boy at first on the basis suggested by the last speaker, but further observation had led him to think this was a mistake.

Tumor of Cerebellum Involving the Abducens Nucleus.—Dr. M. G. Schlapp presented a man, twenty-one years of age, who had come to him about six weeks ago. There was no tuberculosis in the family and he had had no syphilis. About two years ago he had first noticed that at times he would become dizzy and that this would be followed by headache and vomiting. Shortly after this he had fallen out of a wagon and since then the left side had grown weaker. Examination of the eye showed choked disk, weakness of the left leg and an ataxic gait. The ataxia was most marked in the left leg; the knee-jerks were absent; the plantar and abdominal reflexes were present; the pupils were equal and reacted to light; there were no sensory disturbances. A week ago he had developed a disturbance of the conjugate movement of the eyes, which had disappeared in two days. The convergent reaction was, however, all right. He had made a diagnosis of a tumor involving the anterior part of the left side of the cerebellum and in some way affecting the abducens nucleus.

Tumor of Posterior Central Convolution.—Dr. Schlapp presented a woman, forty-one years of age, a Bohemian cigar-maker. She had enjoyed good health up to five years ago. At that time she had fallen down stairs and had sustained some contusions, including one on the left side of the head. Subsequently the right arm and shoulder had become the seat of twitchings, and there were attacks of loss of speech. After three years they had extended over the shoulder and neck to the face and tongue. At first these attacks had occurred once in two weeks, but recently there had been many in a day. Latterly she had also suffered from intense shooting pain in this limb. He had made a diagnosis of a tumor in the posterior central convolution extending back into the parietal lobe. There was astereognosis and impaired tactile and muscular sensibility on the affected side. Pain and temperature sense were not specially disturbed. Dr. Woolsey had operated upon this patient and had found a yellowish and somewhat indurated area, about the size of a dollar, in the posterior central convolution. A section of this tissue was exhibited under the microscope and it showed that the mass removed was not a tumor. Since the operation the strength in the affected hand had improved. She had had four convulsions. The case was presented as having a possible bearing on the question of astereognosis. Apparently the anterior central convolution had not been involved in the growth. It was probable that this convolution was the one having to do with motion, whereas the posterior central convolution had to do chiefly with sensation. In astereognosis the pain and temperature sense are not usually involved, whereas tactile and deep muscular sense are involved. It was known that the two latter do not decussate in the spinal cord, but end in the columns of Goll and Burdock.

Dr. B. Onuf said that he had seen a recent case exhibiting marked conjugate deviation together with a very decided ptosis on the left side and on the right side a paresis of the abducens nerve. This deviation had come on after an apoplectic attack of hemiplegia. He did not think such a case could be explained by the involvement of the abducens nucleus; the lesion was evidently in the region of the third nucleus. It was possible that involvement of the posterior longitudinal fasciculus might explain the deviation. In his case the deviation was permanent. The affection of the right auditory nerve would confirm the theory that the abducens was affected.

Multiple Endothelioma of the Dura.—Dr. Hunt presented this specimen, which was derived from a woman, forty-five years of age, in the Montefiore Hospital. When fifteen years old she had become suddenly deaf. Two years before admission she had be-

gun to suffer from headache and these had persisted. There had been no vertigo. At times her legs would suddenly give way and she would fall. On admission, examination showed that there was a tendency to fall to the right; the right pupil was larger than the left; facial innervation on the right side was deficient; the tongue deviated to the left; the optic nerve showed choked disk, and weakness ot the right upper and left lower extremity was very marked. The tendon reflexes were all exaggerated, but this was especially noticeable in the right arm and left leg. The right patellar reflex only was present. At the autopsy over one hundred tumors were found on the dura, aggregated chiefly about the falx, but extending over the convexity on either side. Four of the tumors were larger than the others. At the base of the brain the dura mater was free, but there were two tumors, the size of a pigeon's egg, occupying the interval between the pons and the medulla and causing a pressure atrophy of the middle peduncles on each side. These tumors were found to be endotheliomata and the vessels showed considerable calcareous deposit. There was no evidence of malignancy.

Gliosarcoma of the Right Frontal Lobe.—Dr. Hunt also showed this specimen, taken from a man, forty years of age, who had been brought to Bellevue Hospital because he had fallen in the street. According to friends, he had been acting very peculiarly for the past four months. He was moderately emaciated and the face was flushed. There was an incomplete left-sided hemiplegia with loss of skin and tendon reflexes on the affected side. He was stupid, but could be easily aroused to answer questions. He showed a strong disposition to turn everything into ridicule. There was no conjugate deviation of the eyes and no aphasia. The pulse was not slow. At the autopsy the meninges were found to be normal, but the convolutions over the right frontal lobe were flattened and very edematous. On making a section into this lobe a large tumor had been found growing in the white substance. It had grown outward and downward into the frontal cortex. The tumor proved to be a gliosarcoma.

Brain Tumors.—Dr. M. Allen Starr opened the discussion on this subject, reporting the following case: The patient was a boy of eleven years, who had come to him after treatment for malaria by other physicians because of the persistence of morning headaches. These headaches had begun in June and had gradually increased in severity up to October 8th, when Dr. Starr had first seen him. The boy was then dull, spoke very slowly, and would drop asleep if left alone for a very few minutes. The left external rectus was a little weak; there was nystagmus and double optic neuritis. He had suffered from vertigo and had vomited twice unexpectedly. His gait was quite ataxic and the left limbs assumed involuntarily abnormal positions. There was no inability to smile, either voluntarily or reflexly. The ataxia of the right leg was very marked and was associated with a peculiar involuntary position of the hand and arm. There was apparently no anesthesia on the left side and no hemianopsia. A diagnosis of tumor of the optic thalamus had been made at once because of these forced positions. Dr. Starr said that he had seen such a case in Meynert's clinic in Vienna. Meynert considered these automatic movements and forced positions as a voluntary correction of a delusional state. The question of operation was not entertained. As the boy's father had died of general paresis the boy was put on mixed treatment and this had been pushed vigorously for a number of weeks. During this time the boy had grown steadily worse and had had several collapses accompanied by a pulse of 40 and rapid breathing. He had been last seen on October 27th, and had been able then to understand what was said, but could not talk at all. He was totally paralyzed on the right side and was able to turn the head only to the middle line. There was apparently no disturbance of sensation on the paralyzed side. The limbs were no longer held in stiff positions, but were relaxed and the tendon reflexes were abolished. There was no complaint of headache. The pulse was 80, the respirations regular, and there was no fever. He died quietly on the following day. The autopsy revealed the presence of a tumor occupying the optic thalamus on the left side, which was enormously enlarged. It was completely infiltrated by a sarcoma. The tumor had apparently compressed the internal capsule and had infiltrated all of the tissue of the segmentum about the corpora quadrigemina. The ventricles were enormously distended with fluid.

Dr. Starr said that this case had led him to look over his private records of brain tumors for the past six years. He had seen in this time 25 cases. Fifteen of the patients were males and ten females. All ages appeared to be about equally liable. The average duration of the disease had been eleven months, which was much shorter than generally stated. The tumors had been distinctly located in 15 cases and it had been possible to operate in 4 cases. No diagnosis of tumor whatever had been possible in 2 cases. One of these was a patient whom he had been asked to see because it was purposed to commit him to an asylum. There was a history of chronic alcoholsm, some headache and morning vomiting; great mental irritability and imperfect memory. At times he was very violent with his family, though perfectly quiet in the presence of others. In the previous month, on two occasions, he had had sudden attacks of coma lasting about half an hour. Two days after this examination the patient had suddenly died and the autopsy had revealed a large tumor occupying the left superior parietal convolution. The other case had been seen in consultation with Dr. Biggs. Several physicians had agreed upon the diagnosis of bulbar paralysis. There was no optic neuritis and no headache. At the autopsy, a small tumor had been found occupying the entire medulla oblongata. Localizaton had been impossible in 8 out of his 25 cases. In 19 an operation had been absolutely impossible, either because of the absence of a diagnosis or because the tumor was inaccessible. The operation had been done in 6 cases and in 2 had been successful in that the tumor had been found, but one of these patients had died. Therefore, there had only been one patient out of 25 who had recovered. In one case, astereognosis had been considered the most important symptom of localization and consequently the parietal region had been freely exposed, but no tumor had been found. In one case in which the tumor had been in the cerebellum Dr. McCosh had operated. To relieve the distention of the ventricles they were tapped and drained. Sixty ounces of fluid a day had been obtained from the lateral ventricles. The patient had finally died, and an infiltrating tumor of the cerebellum had been found. In another case of cerebellar tumor, the ocipital bone had appeared worm-eaten at the operation and had been the seat of such a profuse hemorrhage that further exploration had been considered inadvisable. In a summary of the cases of brain tumor made by him in 1896 it had been shown that about 7 per cent. of brain tumors are operable and that of the cases operated upon about one-third recover from the operation. These earlier statistics had been made up from a large number of cases by different operators and had not been from his own records alone.

Dr. A. J. McCosh said that the case shown by Dr. Starr was an unusually favorable one for operation be-

cause of the accuracy of the diagnosis, the accessibility of the growth and its freedom from vascularity. Most of the brain tumors that he had seen had usually caused considerable hemorrhage and severe shook. The statistics of these 25 cases seemed to him to come more nearly to the truth than the older ones giving a more favorable percentage.

Dr. Leszynsky said he wished to report the further progress of the case reported by him to the American Neurological Association. The patient had been suffering from symptoms pointing to a lesion in the motor area for nearly two years before coming under observation. The tumor had been found at operation to be an endothelioma of the motor cortex. The operation had been done two years and a half ago and, although the patient had relapsed more or less into a hemiplegic state, he had practically recovered. The localization in this case had been exceedingly accurate. No untoward result had followed the operation and no additional damage had been done to the brain by the operation. The patient was still engaged as an accountant.

Dr. Onuf reported a case in which the localization had been very satisfactory. The history had begun in July, 1901, with slight jerkings of the shoulder and hip, followed by weakness of the left leg and arm. About two months after the onset of the symptoms the speaker had seen him and, although suspecting brain tumor, had placed the man on vigorous antisyphilitic treatment for two weeks. A peculiar feature had been that there was chiefly an affection of the abductors, flexors and extensors of the hip, while the extensors of the knee had been less affected, and the muscles of the feet hardly at all. The jerkings had been purely of the Jacksonian type. The case was remarkable because of the absence of headache and local tenderness. The diagnosis had been made, chiefly on the predominance of the affection of the central part of the extremities, of a tumor situated between the shoulder and hip centers, probably quite near the cortex. Immediate operation had been urged, but it had not been done for three weeks. The tumor had been found directly beneath the trephine opening. There was much shortening, so that a sound could be introduced for two inches without encountering resistance. The microscope showed the tumor to be a gliosarcoma. It had been impossible to remove all of the tumor.

Dr. Schlapp said that in his specimen there was an arteriosclerosis with an increase of gliar cells and the deposition of calcareous material. He had not made the diagnosis of tumor involving the abducens nucleus entirely on the conjugate deviation, but the fact that the left side of the face had been weaker than the right had seemed to confirm that view.

Dr. Joseph Fraenkel said that he had seen a few days ago a boy of about eighteen, who claimed to have been well until struck in the back of the head by a swinging door. After this he had developed paralysis of the right third nerve, followed soon afterward by hemiplegia. He had been operated upon and the base of the brain searched for a basal cyst, but none had been found. He had then been admitted to the Montefiore Hospital. There was paralysis of the left upper extremity and an enormous contracture, with less marked paralysis of the left lower extremity and some slight optic atrophy. Subsequently inquiry had elicited the fact that his companions had noticed long before the accident that the boy showed a peculiar tendency to laughter. Dr. Fraenkel recalled a case which had exhibited similar automatic movements to those reported in Dr. Starr's case. He had come to the conclusion that the tonus of the muscle was the most important factor in connection with the production of reflexes. He would like to know how absence of the reflexes could be explained in Dr. Starr's case.

Dr. Joseph Collins exhibited a photograph of an enormous tumor of the frontal convolution, which had been diagnosticated by an eminent neurologist and by himself as a tumor of the pons. His experience had gone to show that brain tumors are far more inoperable than was generally believed. Statistics had seemed to show that about 7 to 10 per cent. were operable, but when one came to sift these it was found that only about 3 or 4 per cent. were operable. In his own experience but one case had been successfully operated upon, although the operation had been many times essayed. Dr. Bramwell of Edinburgh had contended that his own very large experience had utterly failed to confirm the statistics given by others regarding the operability of brain tumors.

Dr. Starr closed the discussion. He did not feel like subscribing to the statement of the last speaker concerning the almost universal inoperability of brain tumors, for in his own series of 25 two had been distinctly localizable and operable. Accidental hemorrhage had caused death in one of these cases and the other ought to live the usual length of life with only slight disability. It was true a great many cases of brain tumor successfully operated upon were reported while many unsuccessful ones are not reported. Dr. Bramwell's statements were not borne out by his experience, for he had published 61 cases of brain tumor that had occurred in his own practice and of this number there had been at least 7 that could have been successfuly operated upon. Discouraging as the statistics were, it was right to operate upon every case of brain tumor having a distinctly localized and accessible tumor. He believed that if in the case presented by him at this meeting the operation had been consented to when first advised, the patient would have recovered without any disabliity. The conjugate deviation referred to by Dr. Schlapp might occur not only from a lesion of the sixth nerve nucleus, but from anything which interferes with the posterior longitudinal fasciculus between the sixth and third nerve nucleus.

SOCIETY OF DERMATOLOGY AND GENITO-URINARY SURGERY OF NEW YORK.

Stated Meeting, Held January 10, 1902.

The President, Robert Holmes Greene, M.D., in the Chair.

Keratosis Palmaris and Plantaris.—Dr. Lapowski presented a boy, aged seven years, with an eruption which appeared on both palms, without any prodromal symptoms, when he was three months of age. Several months later, before vaccination, the soles also became affected. The eruption on both palms and soles has since persisted. His family history is negative. When nine months old he was vaccinated. This was followed by an eruption which lasted several weeks, the palms and soles remaining the same and unaffected by the vaccinia. He has had none of the eruptive diseases of childhood. Last summer he had an acute attack of malaria which lasted six months and which was followed by swelling of both submaxillary glands. Two years ago the epidermis of both palms and soles was greatly thickened, forming a dense plate. The thickening was even, the surface was smooth, and there was no excessive sweating, or cracks. A delicate hyperemia extended beyond the border of the keratosis. Both soles were similarly affected. During the first years diachylon ointment and salicylic acid (10 per cent.) and ichthyol rubber plaster (20 per cent.) were applied externally and Thomson's solution of phosphorus (gr.

1/300 was given internally with no effect. During the past six months thyroid-extract tablets (gr. ijss, English make), one-half to three a day, have been given and diachylon ointment and lanolin have been applied. Within three months after the institution of this treatment remarkable improvement followed. Examination of the urine by Dr. Sondern showed a concentrated character, moderate indicanuria and a high nitrogenous output for a child of his age.

Dr. George T. Elliott said that nearly all cases are greatly benefited by salicylic acid and diachylon ointment. He had seen a complete cure, with no recurrences after two years, follow the use of salicylic acid and glyceride of lead in lanolin with 5 per cent. menthol added.

Dr. Goldenberg presented a case of lupus vulgaris disseminatus. The patient was a boy, six years old, the youngest of five children, who, like their father and mother, enjoyed perfect health. The patient never had symptoms of scrofulosis, but seems to have been rachitic, not being able to walk until three years of age, and since then has been mentally rather weak. The present eruption began about two years ago, following an attack of measles. It was first localized on the face and then spread over the body. There is a dull red patch on the right cheek the size of a ten-cent piece, soft to the touch, the center cicatrized, the border well raised above the surface. A number of small transparent, apple-jelly tubercles, the size of a pin-head, are found on the flexor surface of the arms. On the lower extremities and hands there are a number of patches similar to the one on the face, some of them scaly, others covered with crusts. A particularly large one, very firm and crusted, occupies the region of the buttocks, and on the right hand there are two tumors papillary in character. There are also some lupus nodules on the site of the vaccination mark, the boy having been vaccinated six months ago. There is a very small superficial ulceration on the mucous membrane of the right side of the lower lip.

Dr. Leviseur remarked that as regards therapeutics electrolysis would be most effective treatment. It causes but little pain, is followed by slight reaction and is very conservative in so far as it does not produce unnecessary destruction of healthy tissue. The operation is performed in the ordinary way, the needle being connected with the negative pole with a current of about thirty volts and two milliamperes. Dr. Cocks said that two years ago he had had the opportunity of seeing a similar case, which was treated by the X-rays with remarkable success. Dr. Goldenberg believes in the efficacy of good hygiene, the administration of cod-liver oil and creosote. He has at present at the Mt. Sinai Hospital another case of lupus which is being treated with the X-rays and which he expected to present at a future meeting.

Nævus Pilosus.—Dr. Lapowski presented this case and said that the child's mother in her third month of pregnancy was scratched on the cheek by a kitten. The nævus as seen on the child's face is upon the cheek and is covered with very fine gray hair, thus suggesting maternal impression. There were two other nævi upon the body. Dr. Otis is not inclined to believe in any stigmata of the kind mentioned. Dr. Cocks remarked that the fetus is already formed at the second month and any maternal impression must occur before that time. Dr. Leviseur asked for advice regarding the use of electrolysis, remarking that the case was not a good one for this method of treatment, because the hairs were very fine and situated closely together, so that one might as well destroy the nævus *in toto* which then would result in a very disfiguring scar.

Lupus Erythematosus Disseminatus.—Dr. Goldenberg presented this case. The patient is nine years of age, with a negative family history as regards phthisis. At the age of six years, the disease appeared on both ears which had recently been frostbitten. On the body it was first observed about a year ago. He is poorly nourished, cachectic, with a hoarse voice, coughs considerably; there is consolidation of the left apex. Both ears are enlarged, hard, red, infiltrated, uneven, and covered with firmly-adherent scales. There are a great number of small, punched-out scars distributed over the ears, and a small number of fresh lesions, namely, pustules, covered with yellowish crusts. The same punched-out white scars are found on both forearms and on the lower extremities. There are also some fresh lesions, deep-seated papules, some with a small vesicule formation in the center, some pustular, others with crusts, which when removed show a deep necrotic focus in the center. The picture of the disease corresponds in every detail to the one described by Boeck, who has called attention to the fact that even after the lesions are healed the diagnosis can yet be made from symmetrical, punched-out scars situated on the ears, arms and legs. The disease is probably identical with Barthelemy's folliculitis, Brocq's *folliculites disseminées symmetriques des parties glabres à tendances cicatricielles*, Bronson's acne varioliformis, Pollitzer's hydradenitis suppurativa destruens, and belongs to the tuberculides of the French.

Dr. George T. Elliott said that to-day everything is tuberculide; sixty years ago everything was scrofulide. The case shown by Dr. Bronson was exactly like the present one. It was investigated by Dr. Fordyce and was found to consist microscopically of granulomatous lesions. There was no history of tuberculosis. The history of the case pointed to an intestinal toxemia. It has been stated that 48 per cent. of the cases were in some way connected with tuberculosis, but what had became of the other 52? They developed under the same conditions, took the same course, and the clinical and pathological histories were absolutely the same. He advised dropping of the name of tuberculides and standing strictly on pathological grounds.

Dr. Whitehead said that Dr. Johnston had shown a similar case and called it necrotic granuloma. He thought the relation of tuberculosis with these cases was rather doubtful. Dr. Goldenberg's case was the only one he had seen in which there was a distinct history of tuberculosis and this was considered an interesting feature of the case.

Dr. Lapowski believes in the tuberculous origin of these tuberculides, a focus being present, if not in the lungs, in some other internal organs, such as the suprarenal glands, the pancreas, the thyroid, etc.

Addison's Disease.—Dr. E. L. Cocks presented a man, aged fifty-three years, who had a chancre in 1871 which lasted six months. He claimed that he had no other syphilitic lesion until 1879. Several dark spots appeared on different parts of his body and four months later the eruption became generalized. The spots disappeared and then reappeared at intervals. He did not consult a physician. From 1877 to 1892 he was perfectly well with a clear skin. During the early part of 1892 he was suddenly taken ill and was unable to leave the house for two months. His physician said he had some of the symptoms of typhoid fever, but admitted that the case was rather puzzling. Nine years of fairly good health followed. In October, 1901, he first noticed the present eruption. Dr. Cocks first saw the patient November 25, 1901, when he was complaining of irritability of the stomach, unaccountable languor and debility, loss of memory, and dyspnea. At two different examinations the pulse was found to run from 36 to 40 per minute. At times nausea followed vomiting and constipation alternated with diarrhea. He had

slight headache, tinnitus aurium at times, and insomnia most of the time. The pigment was found in the rete Malpighii. The mucous membrane of the mouth showed several pigmentary spots. The pigmentation was beautifully shown on the glans penis. He had no medicine for six years until time of observation. He has had arsenic for two weeks only. The speaker thought that from the symptoms, one could very readily make the diagnosis of Addison's disease. The patient has been receiving ninety grains of suprarenal extract a day and the eruption is rapidly clearing up and the other symptoms are also much better.

Vesical Calculus.—Dr. H. H. Morton presented two specimens. The first was removed from a boy, eight years of age. He had had pain and frequent micturition since he was a very small child. He was a masturbator. The urine was alkaline in reaction and contained pus. While the patient was under the influence of chloroform the searcher detected a stone. On August 20, 1901, a suprapubic operation was performed. After the operation the temperature ranged from 103° to 105° F. for ten days. The patient lost flesh and weight. A malarial taint was suspected and quinine was given, eight grains per day. The temperature began to go down and improvement in the symptoms followed at once. The wound closed four weeks after the operation. He called attention to the following points: (1) History of masturbation as a cause for stone; (2) examination under an anesthetic; (3) choice of operation; suprapubic chosen on account of the size of the stone; (4) continuance of high temperature, resembling the septic type, due to malaria.

The second specimen was removed from a boy, seven years of age. He had been idiotic since birth and he always had been troubled with dribbling of urine. He holds the penis because of the pain and when he lets go urine passes in a large stream and with force. At times the stream is shut off suddenly. Priapism was very persistent. Blood was not found in the urine, but there was pus present. December 17, 1901, a perineal lithotomy was performed. The stone was difficult to grasp on account of its size and the wound had to be enlarged to permit of its extraction. On December 28th the perineal tube was removed. January 4th the patient was up and running about the ward. The wound had not entirely healed and the urine still passed through it.

Dr. Greene referred to a report in which it was stated that large crushing instruments were admitted through the urethra in children aged three, four and five years of age. It has not been attempted as much in this country as abroad.

Dr. Otis said that it would certainly be difficult to crush a stone the size of the one presented in so young a child and that it would take a long time; yet, he believed that it could be done and without any laceration of the parts whatever.

Dr. Von Glahn stated that Dr. Marc, at Wildungen, did 400 operations every summer for stone, crushing them in every instance; the patients were out in four or five days.

Litholopaxy Under Cocaine.—Dr. Swinburne showed a specimen which he had removed from a patient at the Good Samaritan Dispensary under cocaine, the patient walking home after the operation. He was a man, sixty-two years old, who had been suffering from frequent and painful urination by day; it was not so frequent at night. Sometimes there was blood in the urine, which was cloudy. Examination with the Thompson searcher revealed the presence of a calculus in the bladder. He gave the man urotropin, and treated the bladder locally for two or three weeks hoping to get him in better condition. During that time he noticed that his urethra was quite tolerant to urethral instruments and the idea occurred to him that a litholopaxy could be successfully performed under cocaine. With this end in view he proceeded to get him used to the manipulations he would have to go through when he came to perform the operation. At each visit, twice a week, after washing out the bladder with a saline solution, he would leave in some of the fluid and insert the lithotrite and grasp the calculus. One day he discovered the presence of a second stone. After doing this he would remove the instrument and insert a No. 22 evacuating tube, attach it to a Chismore evacuating bottle and go through the manipulation of washing out the fragments. No reaction ever followed. This was done for three or four weeks. Early in June he attempted the operation. After washing out the bladder he withdrew the eye of the catheter into the posterior urethra and slowly instilled about six drams of a two-per-cent. solution of cocaine into the posterior urethra and bladder and left it in place. He then injected a syringeful of the cocaine solution into the anterior urethra and had the patient retain it; then, leaving the cocaine in the bladder he filled the latter with sterile saline solution. Unfortunately, he used a small Bigelow lithotrite and crushing was very slow; finally, it became jammed; he removed it and introduced a larger instrument, Keyes, which very quickly reduced the fragments of one calculus sufficiently to remove them. This took about three-quarters of an hour and, as the influence of the cocaine was wearing off, he did not attempt to crush the second stone. The patient suffered no pain and was sent home and told to go to bed for forty-eight hours. For four weeks he treated him in the same manner and the patient brought several small fragments which had come away when he urinated. In July he repeated the operation, removing the second calculus, using a moderate-sized Keyes instrument and thought he had removed every fragment. The patient felt so well he did not go to bed as ordered. No reaction followed and in a week he returned to the Dispensary. His urine was clear, the intervals of urinating were normal, and he reported himself as being thoroughly well. On October 30th the patient returned saying that he was again suffering from pain and frequent urination and with cloudy urine. The searcher detected nothing, but with the evacuator and wash-bottle he obtained a small calculus. Since then the patient has been perfectly comfortable.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Stated Meeting, Held January 4, 1902.

The President, Howard Lilienthal, M.D., in the Chair.

Acquired Dextrocardia.—Dr. Charles Schram presented a patient whose heart is in the right cavity of his chest, apparently as the consequence of a prolonged process of tuberculous tissue destruction and consequent pulmonary contraction. The slow-running tuberculous process resulted in the so-called cirrhotic lung, which in retracting drew the heart with it, pleural and pericardial adhesions being the intermediary factors aiding in the displacement. The patient, twenty-four years of age, was born in Germany, but has been in New York since the age of five. He is a draughtsman of metal ornaments, who has never smoked and who uses stimulants only moderately and with his meals. He denies venereal history. Both his parents are partial deaf mutes and a brother is also a deaf mute. This is evidently an hereditary condition. There is, however, no tuberculous history in the family. At the age of four the patient had measles followed by inflammation of the lungs and some months later he developed scarlet fever. When eight years of age, he had another attack

of inflammation of the lungs, which lasted for some weeks and seems to have ended, according to the history, by lysis and not by crisis. He considers this to have been his last serious attack of illness. Five years ago he had acute articular rheumatism, the joint symptoms being confined to the right knee. He was in bed only for three days, but does not seem to have entirely gotten over his arthritic inflammatory condition. He has had joint pains in his knee ever since, whenever the weather is changeable.

Pulmonary Symptoms.—Ever since his attack of pneumonia some sixteen years ago he has had a tendency to recurrent bronchial attacks. There was scarcely a year that he was free from a series of these. They usually began in the late fall and lasted for some months. During the first weeks of the illness he coughed up thick, abundant and somewhat greenish-yellow material. The expectoration gradually diminished after a month or so and with it the inclination to cough, but in milder form his cough persisted during the whole winter. He has never expectorated blood. He never suffered from night-sweats and does not seem to have had the chilly sensations or the tired feeling that accompanies febrile conditions. During these bronchial attacks he had general physical and mental depression. Anorexia was usually marked, especially at the beginning. Since 1893, however, his attacks have not interfered with his studies or with his occupation, but up to within a year or two he has coughed more or less all the year round. At present, except for rheumatic pains in various joints for which he has come for treatment, he considers his health reasonably good. He has no dyspnea on exertion, except on climbing a number of stairs, when he also has moderate palpitation of the heart. This palpitation is felt on the right side. He dances regularly twice a month, takes great pleasure in the exercise, and finds no special inconvenience in it.

Physical Condition.—His chest is asymmetrical. The left side is deeper than the right, the right side inclining inward where the ribs join the middle third of the spine. There is some flattening below the clavicle. The right shoulder is lower than the left and the right scapula protrudes. The measurement of the left chest in the nipple line at the lower end of the scapula is sixteen inches. The measurement of the right chest at the same line is fifteen inches. The left chest moves more with inspiration than the right. Vocal fremitus is more marked on the right side than on the left, both in front and posteriorly. A diffuse wave-like impulse is noticeable in the fifth right intercostal space about two inches below the right nipple. It is not easy to see unless carefully looked for, but can be felt very well with the palm of the hand. The left chest is resonant, the right chest dull and in part flat in front and posteriorly. There is bronchial breathing, bronchophony and whispering bronchophony to confirm the other signs of pulmonary consolidation on the right side. On the left the respiratory murmur is puerile, showing that this lung is doing compensatory work. No râles are to be heard and the area of cardiac dulness is not determinable, because of the irregular percussion sounds that are obtained over the consolidated lung.

Heart Sounds.—The first sound of the heart seems loudest in the fifth intercostal space, two inches below and one inch to the left of the right nipple. The aortic sound is best heard in the second intercostal space two inches above the right nipple. The pulmonary second sound is best heard at the junction of the right border of the sternum and the third rib. There are no suspicious signs in the heart sounds and certainly no adventitious sounds. The cardiac rhythm is undisturbed and the general heart condition seems excellent. It seems clear that there is at present a cirrhotic lung resulting from repeated acute exacerbations of chronic pulmonitis with perhaps complicating pleuritis of probable tuberculous origin. The condition produced is so serious that it is a little hard to understand how they could have proceeded to the production of so much pathological change without inducing more serious symptoms. It is even a little surprising that the patient has survived them.

Etiology of Dextrocardia.—The late Dr. Loomis enumerated the mechanical elements concerned in producing dextrocardia as follows: There is, first, the restraining forces of the cardiac attachments at the base of the heart; second, the density and resistance of the surrounding tissues; third, the weight of the heart, and, fourth, pressure and traction. All of these elements seem to have been more or less concerned in the case presented. The retracting lung on the right served as the most important displacing factor. After this came the compensatory expansion of the left lung which not only displaced, but turned the heart on its long axis, the organ revolving on its basic attachments as a pivot. According to Osler the abdominal organs are transposed in 70 out of 78 cases of dextrocardia. As the dextrocardia in this case, however, was acquired late in life, there is not any transposition of abdominal viscera. The most interesting feature of the case is that, notwithstanding the great displacement of the heart, there are no symptoms referable to this fact in the patient's general condition. It is hard to understand how so important an organ can be pulled and twisted in the way that has evidently happened to this one and yet produce no annoyance that would call the patient's attention to the condition.

Question of Purulent Effusion.—In discussing Dr. Schram's case, Dr. Daniels said that it seems not impossible that there should have been in this case a purulent pleural effusion following one of the pneumonias and probably due to the pneumococcus. Such cases sometimes occur after children's pneumonias and are evacuated spontaneously through the lung. After these purulent effusions there is a marked tendency to the formation of adhesions and to contraction of the lung. This contraction is a much more active process than the so-called tuberculous cirrhosis of the lung and accounts much better for the serious alterations that have taken place in the tissues in this case. It seems doubtful if any mere cirrhotic tuberculous process would cause as much displacement as has occurred in this case. There is, moreover, in the history of the case an absence of the severe symptoms that would accompany so serious and important a tuberculous process as this. The patient had a tendency to bronchitis every winter, but this could be accounted for much better, perhaps, by the lowered vitality of his pulmonary tissues as a consequence of the lack of respiratory function than by a constantly active tuberculous process.

Displacements by Effusion.—In closing the discussion Dr. Schram said that displacements of the heart frequently occur because of pleural effusion. As is well known, however, these are not permanent. In the present case there is no sputum, the examination of which would disclose the presence of tubercle bacilli and make the diagnosis of pulmonary tuberculosis absolute. There is nothing in the history of the case that would actually demonstrate that a tuberculous process had been at work. This seems, however, the most reasonable explanation of the cirrhotic contractile condition that has ensued and has left one of the lungs almost completely useless for respiratory function.

Tuberculosis.—Dr. F. H. Daniels then read the paper of the evening. This will appear in a subsequent issue of the MEDICAL NEWS.

Hospital Infection.—In discussing Dr. Daniels'

paper, Dr. John B. Walker said that according to the provisions of the new charter for Greater New York no cases of tuberculosis are to be treated at Bellevue after February 1, 1902. This is welcome news to medical men, for in recent years there has come the realization of how serious the infective power of the presence of tubrculous patients may be, when other patients are in the susceptible, run-down condition, so usual in hospital practice. There is no doubt that tuberculosis has been communicated at Bellevue. Last year one of the resident physicians died of phthisis contracted in the Hospital and patients have frequently been admitted without any trace of pulmonary disease who have developed the affection before being long in the Hospital. There is special danger, of course, for patients already suffering from pulmonary affections.

Tuberculosis Communication.—Dr. Potter said that there is no doubt that tuberculosis is communicated at times to other hospital patients. He has himself seen a case of acute tabes enter the City Hospital without any trace of pulmonary affection and after four weeks suffer from slight hemorrhage. This was followed later by other symptoms of tuberculosis and a typical case of the disease developed. The dangers in hospitals are especially concerned with the dust in the wards. It is practically impossible to guard crowded hospital wards sufficiently in this matter to prevent danger of dust contamination. Flying particles bearing bacilli inevitably find their way into the air of the wards and are breathed in by susceptible patients. Many series of bacteriological observations have been made, showing the dangers in this matter. The hospital crowding and the mingling of patients, that render these dangers so serious, must, if possible, be prevented.

Successful Treatment of Tuberculosis.—Dr. Schram said that undoubtedly excellent results can be obtained in the treatment of tuberculosis. The disease is by no means the incurable one that it has been considered. The reported good results in the German sanatoria were at first looked upon with incredulity. The reported cures are, however, no matter of surprise to those who have visited these German institutions. The sanatoria for the tuberculous, for instance, in the Black Forest, are so situated as to provide a constant invitation for patients to go out into the open air. The level walks and the forest paths, with the inviting surroundings, are a constant source of pleasure for the healthy and the sick. There is no need for patients to be driven out, nor urged very much to be in the open air. Simple directions and the inviting surroundings soon do the necessary work and the good effects of being out in the open air almost constantly soon make themselves felt so much on the patient and in such a way as to need no further urging to secure their being out.

Tuberculous Houses.—Dr. Reynold W. Wilcox said that he had recently been engaged in the study of the charts of the Board of Health of New York City which are supposed to show that tuberculosis is worse in certain houses and that where the disease has occurred in a house other inmates are liable to be infected even though they may be no relative of the preceding patient and have had no intercourse with him. In a word, it is said that statistics show that houses become contaminated with the disease to such a degree as to be capable of conveying it to successive tenants. Dr. Wilcox has not found that this contention of the health authorities is borne out by the actual statistics. At times, it is true, deaths from tuberculosis in the families of successive tenants can be found, but after a series of deaths there will then be a cessation of the spell and the contamination, if any were ever present, seems to die out. In a word, it is not a law of disease, but a chance of statistics that seems to be at work in the matter. Dr. Wilcox said that the worst crowded houses in the city are those in which the Chinese live, and yet it is generally recognized that there is no special incidence of tuberculosis among the people of that nationality. It seems clear, then, that it is not crowding of itself, but the presence of other tuberculous patients in the crowded houses that causes rapid spread of the disease. In one case in which a series of deaths had taken place in a family in a crowded apartment house, Dr. Wilcox suggested removal to the upper floor of the same house. Five brothers and sisters had died in the family previously. Two sisters suffering from the disease at the time of the removal were cured and the remaining sister did not develop the disease.

Importance of Sunlight.—Undoubtedly, sunlight is a very important therapeutic agent in the treatment of tuberculosis. Dr. Wilcox's experience would seem to show that the upper floors of houses, because of their greater flooding with sunshine, are less liable to be fostering-places for the disease than the lower and darker floors. This curative property of sunlight and its prophylactic effect are not the discovery of the present generation, however. Dr. Bowditch of Boston, in 1850, insisted very much on the fact that sunlight was the most important natural agent for the treatment of tuberculosis and the only therapeutic agent available for the treatment of all forms of the disease and sure to do them all good.

Tuberculous Peritonitis.—Dr. William R. Coley said that the main purpose at the present moment must be to teach the laity that tuberculosis is not only not incurable, but that the disease if placed under proper conditions has a definite tendency to cure. Some very interesting reflections on this matter are to be found in the history of surgical intervention in cases of tuberculous peritonitis. Professor Koenig in 1884 reported cure of peritoneal tuberculosis by simple abdominal incision. Since then surgeons throughout the world have been performing laparotomy for the condition. Most of them have reported many good results. A recent article by Fenger in the "Annals of Surgery" reviews the benefit of surgical intervention in these cases. After following cases for a number of years, some of them operated upon and some of them left untouched, Fenger concludes that absolutely no good has been done by the operation. A similar conclusion has been forming in the minds of many surgeons for some time. Fenger says that surgeons may be thankful for the justifiable opportunity that has been afforded them to examine tuberculous processes on the peritoneum by direct inspection, but they must now hand these cases back to the physician.

At Home or Abroad.—Dr. Howard Lilienthal said that it is always a sin to send tuberculous patients away from home unless they can be sure to be at least as comfortable in their new quarters as they were at home. This is, of course, not true in the great majority of cases. To suggest to patients in ordinary circumstances that they must leave home is usually to make them dissatisfied, but not to do them any good. Now that we have come to realize that climate of itself means much less in the treatment of tuberculosis than was formerly thought, it becomes still more clear that patients must not be advised to leave home without a thorough consideration of all the circumstances of their cases.

Distribution of Tuberculosis.—In closing the discussion Dr. Daniels said that there are many ways that ordinarily pass unnoticed in which seeds of infection may be carried from place to place. Flies, for instance, have been known to carry virulent bacilli from one place to another. Such material as tuberculous sputum is apt

to be attractive to flies. They light on it and then carry on their legs to neighboring food material extremely dangerous germs. Dr. Daniels finds it difficult to understand that tuberculosis should die out in tenements where it has once secured a foothold. It is possible, however, that a given variety of tubercle bacillus may, after a certain time and under a certain condition, fail in its virulence. Such an experience is not unusual in the laboratory study of tuberculosis. It seems much more likely, however, that the new families that move in and fail to have cases of tuberculosis are specially resistant to the disease and that this accounts for the gap in the statistics.

BOOK REVIEWS.

AN EXPERIMENTAL AND CLINICAL RESEARCH INTO CERTAIN PROBLEMS RELATING TO SURGICAL OPERATIONS. An Essay Awarded the Alvarenga Prize for 1901 by the College of Physicians of Philadelphia. By GEORGE W. CRILE, A.M., M.D., Ph.D., Professor of Clinical Surgery, Medical Department, Western Reserve University; Surgeon to St. Alexis Hospital; Associate Surgeon to Lake Street Hospital, Cleveland. J. B. Lippincott Company, Philadelphia.

THIS book for directness and brevity is certainly a profitable addition to any medical library. As its title indicates, it is a report of a long series of experiments followed by clinical observations into clinical operative problems.

In an excellent and scientifically accurate manner it treats first of the methods of annotation and investigation, so that the reader is fully aware of the basis of the results reached. The problems, the solution of which is attempted, comprise the following: On the effect of severing, and of mechanical irritating the vagi; the research into the effect of intravenous injection of saline solution; the physiologic action of cocaine and eucaine; the effect of temporary closure of carotid arteries. Each of these problems is handled, first, with preliminary remarks and a review of literature, next, with an account of experiments followed by a summary of experimental evidence, and, finally, with a statement of the clinical application of the results. Thus, it will be seen that no pains have been spared to weigh each question step by step until a definite conclusion was reached.

A MANUAL OF THE PRACTICE OF MEDICINE. By FREDERICK TAYLOR, M.D., F.R.C.P., Senior Physician to and Lecturer on Medicine at Guy's Hospital, London. Sixth Edition. P. Blakiston's Son & Co., Philadelphia.

THIS is the sixth edition of Dr. Taylor's work. The preface to the first edition was written in January, 1890. It has evidently won for itself many friends in these eleven years. The secret of the popularity of Dr. Taylor's book seems to be its thoroughly practical character and its inclusion in comparatively small space of an excellent digest of what is useful in medicine. In the first edition Dr. Taylor announced his intention of devoting most attention to the description of symptoms, to diagnosis, to prognosis and to treatment, feeling that they are the divisions of the subject which answered to the idea of practice. Etiology and pathology are also considered, but the latter is not so fully dealt with as in works devoted especially to it.

In the present edition the author announces that the subjects most fully revised are malaria, plague, encephalitis, leucemia and the examination of the blood. Certain subjects hitherto untreated in the work find a place in this edition. Among them are the interesting titles, myasthenia gravis, paramyoclonus multiplex, acroparesthesia and acrodactylia, and polyorromenitis. This last term is a synonym for polyserositis. Both are names given to the condition of simultaneous inflammation of two or more of the four great serous membranes—pericardium, pleuræ and peritoneum—an association to which attention has been especially called of late by Italian writers. The book is printed in England and so, perhaps, the omission of some of these new terms from the index should not be laid at the door of the American publishers.

THE STANDARD MEDICAL MANUAL. A Handbook of Practical Medicine. By ALFRED S. BURDICK, M.D., Editor of Medical Standard; Junior Professor of Practice in the Illinois Medical College. G. P. Englehard & Co., Chicago.

THIS is a very handy reference book of practical medicine with the subjects arranged alphabetically, thus facilitating ready consultation. It is not ambitious, for its name "standard" applies only to the fact that its author is the editor of the "Medical Standard" and that the book is issued in connection with the medical journal. The work is of very practical character and is calculated to be eminently helpful, especially to the busy general practitioner who does not want a treatise, but suggestive points at a moment's notice. The volume is very presentable in appearance and will doubtless find a place on many consultation shelves, not among the learned tomes that collect dust and are opened a few times a year, but among the books that are constantly at hand for ready reference.

TYPHOID FEVER AND TYPHUS FEVER. By Dr. H. CURSCHMANN, Professor of Medicine, Leipzig. Edited with Additions by WILLIAM OSLER, M.D., Professor of the Principles and Practice of Medicine, Johns Hopkins University, Baltimore, Md. Authorized Translation from the German, Under the Editorial Supervision of ALFRED STENGEL, M.D., Professor of Clinical Medicine in the University of Pennsylvania. W. B. Saunders and Company, Philadelphia and London.

DR. STENGEL'S declaration in the preface to the first volume of the translation of the Nothnagel series that the excellence of the monographs issued under the editorship of Professor Nothnagel has been recognized by all who are sufficiently familiar with German to read his works will be re-echoed by all students of medicine. They will also be glad to think that the opportunity is to be provided even for those who do not read German to enjoy and profit by the greatest of modern encyclopedias of medicine.

The best index that the Nothnagel series is to be worthily done into English is afforded by the fact that this first volume has for its editor Professor Osler and that he has been encouraged to make such additions to Professor Curschmann's monograph as will bring the subject up-to-date and make it more helpfully practical for American physicians. For those who know Professor Osler's thoroughness there will be no need to add that his work as editor has been taken seriously and that some of the additions constitute important features of the American translation. If this volume is a fair sample of those that are to follow, then the English-speaking medical profession may well be congratulated on the fact that editors and publishers are a unit in the effort to give them what is best and latest in medicine in this work.

Some of Professor Osler's additions made with Professor Curschmann's consent deserve to be mentioned. The chapter on the bacteriology of typhoid fever has

been thoroughly revised and new material added. The distribution of the typhoid bacilli, especially in the urine, in the rose spots, and in the blood, has been noted. The literature on the localized lesions due to the bacillus, particularly of the bones, meninges, heart, pleura, bladder, and so forth, has been carefully revised and brought up to date. Thayer's exhaustive study of the state of the blood has been utilized. The surgical complications of the disease have been very fully considered with the aid of Keen's monograph. The chapter on perforation and peritonitis has been rewritten, as has also the section on the hepatic complications of typhoid fever.

These constitute only some of the American additions. Professor Curschmann's monograph originally was a most exhaustive study of typhoid fever, thoroughly practical in character. The additions have been necessitated by work done since Curschmann's original publication and by so much the American surpasses the German edition. It is evident that no effort has been spared by the American editor to let nothing pass that might be of practical interest in the recent literature of typhoid fever.

The publishers' work in the volume has been very commendably done. The colored plates illustrating the characteristic eruptions of typhoid and typhus fever bring out very well both what is similar and what is differential in the two exanthems. This is manifestly the first volume of what is to form a striking contribution to medical literature in English. The publishers' plan of selling each volume separately and not insisting on a subscription to the whole work in order to obtain volumes of interest is especially to be commended. Medical publishing in America has reached the place where subscriptions are not necessary to insure that large medical works shall afford due returns.

Phototherapy. By Prof. Niels R. Finsen of Copenhagen. Translated from the German Edition and with an Appendix on the Light Treatment of Lupus by James H. Sequeira, M.D., Lond., M.R.C.P. Edward Arnold, London.

This work consists of Finsen's three papers published at different times on "The Chemical Rays of Light and Smallpox," "Light as a Stimulant," and "The Treatment of Lupus Vulgaris by Concentrated Chemical Rays."

Prof. Finsen's work is almost too well known to need much comment. Although the Nobel prize was not, as was prematurely announced, conferred on him, his discoveries in phototherapy are some of the most practical advances made in medicine during this last decade.

In these three papers can be seen the gradual development of his ideas with regard to light as a therapeutic agent. At first, in smallpox his investigations were tentative, later came the assurance that in light there was a great remedial agent. The book represents a landmark in medicine and doubtless will be one of the little books referred to by future generations as an original work well worthy of preservation.

A Manual of Clinical Laboratory Methods. By John B. Nichols, M.D., in charge of Clinical Laboratory, Garfield Hospital; Hematologist to Columbian University Hospital; Professor of Normal Histology in Medical Department of Columbian University, Washington, D. C. William Wood & Co., New York.

The importance of laboratory methods as aids in the diagnosis of disease has called into the field an army of workers whose investigations, being published in numberless medical journals, are not readily available for the student and general practitioner. Books which present such material in a form for ready reference, with the proper selection of those methods which have stood the proof of clinical tests, are therefore of value.

The work in question is a book of this class and its purpose can best be stated in the words of the preface: "To present in practical and systematic form the most important laboratory methods employed in clinical medicine. Covering established methods, it cannot profess to present much that is new or original, or to cover a field not already occupied, but must base its *raison d'être* in the collection of numerous technical procedures within a small compass and presentation of the subject in a manner convenient and clear to students and practitioners of human medicine."

A perusal of its contents shows that these ideas have been well carried out. The subject-matter is condensed, but this does not prevent the mention of details that are either new or necessary to the general understanding of the topic in question. The author includes in his book the consideration of the blood and the technic of its examination, the stomach and its contents, the feces and intestinal discharges, the sputum, and the urine. Pathological fluids, calculi, and parasites are also treated and chapters are devoted to clinical bacteriology and autopsy methods. In each examination the well-recognized methods are arranged in such a manner as to form a good working manual. The one fault to be found in the make-up of the book is its lack of sufficient illustrations, which in a work of this kind are most essential.

The Mental Functions of the Brain. By Bernard Hollander, M.D., Freiburg, M.R.C.S., L.R.C.P., London. G. P. Putnam's Sons, New York and London.

This is an interesting work by one who has made a wide search of literature. Many hundreds of clinical histories are collected and conclusions reached, which if not entirely sound, are suggestive and almost stimulating.

Had the author been less disposed to find fault with the honest, although perhaps incorrect, work of others, we should feel more tolerant toward the attitude he himself would adopt, but there is so manifest an air of special pleading of his own that one is less liable to pay attention to the conclusions there perhaps is warranted.

Phrenology in its modern dress will need a more logical and modest exponent if it would expect a hearing.

THE SURGICAL TREATMENT OF ASCITES DUE TO CIRRHOSIS OF THE LIVER.[1]

BY GEORGE EMERSON BREWER, M.D.,

OF NEW YORK;

INSTRUCTOR IN SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS; JUNIOR SURGEON TO THE ROOSEVELT HOSPITAL, AND ATTENDING SURGEON TO THE CITY HOSPITAL.

IN RESPONSE to an invitation from the Chairman of this Section, I will present for your consideration and discussion this evening a brief review of the facts which have been gathered during the past five years bearing upon the surgical treatment of cirrhosis of the liver.

Cirrhosis of the liver is admitted by all to be an incurable disease, ascites, enlargement of the spleen and hemorrhages into the alimentary canal constituting the terminal symptoms of this condition.

Dr. W. Hale White, in Guy's Hospital Reports for 1892, from an analysis of 34 cases of ascites which were followed to the end, and in which autopsies were made, concludes that the occurrence of ascites in cases of uncomplicated cirrhosis of the liver is of the gravest prognostic importance, the average duration of life being only about eight weeks after the first tapping; the patients who survived numerous tappings were generally found at the autopsy to have lesions other than those of uncomplicated cirrhosis. This view is also confirmed by H. Campbell Thompson in an article which appeared in *The Lancet* for July 20, 1901, in which as a result of 18 autopsies he concludes that cases of cirrhosis which survive numerous tappings are complicated by perihepatitis, chronic peritonitis, or some other pathological lesion which acts as a causative factor in the production of the ascites. Without quoting other confirmatory opinions it is safe to assume that a patient with cirrhosis of the liver who reaches the stage of ascites has before him a very short lease of life. While medical treatment can do much to relieve the distressing symptoms occurring in the early stages of this disease and judicious care and medication may perhaps in certain instances arrest its progress, in the presence of these grave terminal symptoms no drug or method of medical treatment is of any value whatever in averting the inevitable fatal termination.

Apparent recoveries occurring after the appearance of ascites have, however, been occasionally reported; but such recoveries are so rare that they may be justly regarded as medical curiosities. Autopsies, in cases of this kind, almost invariably show the presence of dilated, anastomosing branches between the portal and systemic venous circulation. The normal anastomoses between these two systems have been described by Sappy to be veins passing from the upper surface of the liver, between the two layers of the coronary ligament, to the under surface of the diaphragm, anastomosing there with the radicals of the phrenic vein, one or more veins accompanying the round ligament of the liver anastomosing with the internal mammary and deep epigastric veins and also veins in the regions of the retroperitoneal, esophageal, and hemorrhoidal plexuses.

Telma of Utrecht, after a number of postmortem observations, conceived the idea of increasing this anastomosis by creating adhesions between the surface of the liver and the diaphragm, the surface of the spleen and the adjacent parietal peritoneum, and between the great omentum and the anterior abdominal wall.

The first operation of this kind was performed by Vandermeule in 1889, and consisted in opening the abdominal cavity, evacuating the fluid and stitching the omentum to the anterior abdominal wall. The patient died of shock. The second operation was by Schelkly in 1891, same procedure. His patient died on the fourteenth day. A third case, operated on by Lens, recovered from the operation but showed no improvement in the symptoms.

The next report on the subject was furnished by Mr. Rutherford Morison of Newcastle-on-the-Tyne, who, unaware of the suggestion of Telma or of the work of the Continental surgeons, after numerous postmortem observations determined to favor Nature's method of cure by a far more complete operation than any previously employed. He proposed the following procedure: Under general anesthesia open the abdomen and evacuate the fluid, then rub the upper peritoneal surface of the liver and the under surface of the diaphragm with gauze sponges until raw, freely-bleeding surfaces are produced. The same procedure should be carried out on the outer surface of the spleen and its adjacent peritoneal surface. Finally, stitch the great omentum to a freshened peritoneal surface on the anterior abdominal wall. A glass drain should be introduced to the lower part of the pelvis through a separate suprapubic wound. The upper wound should then be closed and dressings applied. The fluid which collects in the pelvis should be frequently pumped out through the glass drainage-tube for a week or ten days until the daily secretion is markedly diminished. The tube may then be removed and the wound allowed to heal.

The first case in which he carried out this procedure was a doubtful one, the diagnosis of cirrhosis not being established. The patient recov-

[1] Read before the New York Academy of Medicine, Thursday Nov. 21, 1901.

ered from the operation, but there was no improvement in her symptoms and she died nineteen months later. His second case was a brilliant success. The patient recovered from the operation and was apparently completely restored to health. She lived two years in comfort and died from an attempt to repair the ventral hernia which followed the first operation. A very complete autopsy was made, a description of which I will give in the author's own words:

"At the postmortem Mr. W. G. Richardson removed the whole of the abdominal viscera and the parietes excepting the skin. He then injected the whole from the trunk of the portal vein. The liver, spleen and intestines seemed to be attached to the parietes chiefly by small, band-like adhesions. Many of these seemed to contain little except a blood-vessel, and in several of them such a vessel was four inches in length. The omentum was also firmly adherent to the abdominal wall by strong bands. In all of these adhesions innumerable injected vessels are readily seen passing from the omentum and viscera to the parietes. Many of them are fully the size of the radial artery. This specimen establishes our belief that an efficient anastomotic circulation can be brought about by operation. There can be no doubt that this patient was cured of ascites and that useful life was prolonged for her for two years by the operation."

In a subsequent article which appeared in *The Lancet* for May 27, 1899, Morison reports two additional cases, one not surviving the operation; the other was completely successful, the patient being alive at the end of two years without ascites.

While Morison's operation was not the first, as the idea was original with him, and as his method differed essentially from those of the Continental surgeons, and as he succeeded in curing two out of his four patients, in one instance being able years afterward to secure an autopsy which conclusively demonstrated the correctness of his views, he is, I think, entitled to the credit of establishing this new method of treatment.

As a result of the publication of Morison's successful operations there was awakened a very considerable amount of professional interest, and during the past three years quite a large number of articles on the subject have appeared and numerous cases involving operation have been reported by various surgeons.

It is to be regretted that in many of these reports little care has been taken in giving details in regard to the clinical history or methods of operation which would enable us to form more definite ideas as to the causes of mortality and the conditions which favor the success or failure of the procedure. As notable exceptions to this may be mentioned the report published by Dr. Robert F. Weir in the *Medical Record* for Feb. 11, 1899, in which he gives us not only a clear and comprehensive description of his case, but also a masterly review of the literature of the subject which had appeared up to that time; the article by Dr. F. Tilden Brown in the Medical and Surgical Report of the Presbyterian Hospital for 1900, in which he records the complete history of a patient cured by operation and also the paper by Packard and Le Cont published in the *American Journal of the Medical Sciences* for March, 1901. In this latter communication 22 cases are reported, from which the authors conclude that the operation is not necessarily accompanied by a high rate of mortality, and encourage us to believe that recovery, at least from the ascites, may be expected in a fair proportion of cases.

Adverse criticism, however, has not been wanting. The most recent contribution to that side of the subject is the article by Dr. H. Campbell Thompson, published in *The Lancet* for July 20, 1901. In this the writer states that it is his opinion that in no case has ascites due to uncomplicated cirrhosis been cured by operation, but that the successes have been in cases in which the ascites was due to some complicating lesion, such as perihepatitis or chronic peritonitis. While such an opinion unsupported by clinical or pathological facts should not influence us in our judgment regarding the value of this operation, it is to be regretted that in the majority of reported cases no data are given which would enable a reviewer successfully to controvert such a statement. It is therefore suggested that in order to arrive at definite and accurate conclusions in regard to the value of this operation, future reports should give us the age and sex of the patient, history of syphilis, tuberculosis, alcohol or peritoneal inflammation, duration of ascites, number of tappings, condition of heart, lungs and kidneys, exact condition of abdominal viscera observed at operation, anesthetic used, method and duration of operation, method of drainage, subsequent treatment, immediate and remote result.

The analysis of 40 or 50 cases fully reported in this manner would enable us to estimate justly the value of this procedure and form definite ideas regarding its mortality, the most favorable time for surgical intervention, as well as the most approved methods of procedure.

In the writer's opinion the operation is still in its experimental stage. Sufficient data are not at hand to enable us to form definite and lasting conclusions. At present there is apparently a high rate of mortality, due, I believe, to the fact that the majority of physicians are unwilling to advise this method of treatment except in cases in which all hope has been abandoned.

In the accompanying table I have endeavored to present the important facts as far as I have been able to obtain them in 60 cases. In many of the reported cases the histories are so imperfect that few facts of value could be gleaned. A large number of these cases have never before been published but have been obtained by the writer by personal communication. I have desired in the arrangement of this table to suggest a plan of

reporting these operations which will bring out the salient facts just referred to and which will enable us later, when a sufficient number of cases have been collected, to estimate justly the real value of the procedure. I desire before presenting this table to report briefly my own experience in this operation, which, although somewhat discouraging, has not convinced me that the operation may not be of value in more carefully selected cases.

Case I.—A woman, aged fifty-six years, admitted to the medical department of the City Hospital in the spring of 1899 suffering from ascites. There had been a prolonged history of alcoholism; no definite syphilitic history. Previous to the development of the ascites there had been a long period of ill health, the symptoms of which were gastric disturbances, shortness of breath, anemia and general weakness. She was under observation for several weeks, during which time she was tapped on one or more occasions. The urine was abundant, containing a trace only of albumen and hyaline casts.

Operation under ether anesthesia. Median incision in upper segment of abdomen. Large amount of fluid evacuated. The upper surface of the small, nodular liver and the outer surface of the spleen, together with the opposing parietal peritoneal surfaces, were vigorously rubbed with sterile gauze until they bled freely. The parietal peritoneum on each side of the abdominal wound was also rubbed in the same manner, and the omentum drawn down and firmly held in contact with the denuded surface by means of sutures which closed the abdominal wound. A smaller abdominal incision was next made just above the pubes and the rest of the fluid siphoned out. A glass drainage-tube was introduced through the lower opening into the pelvic cavity. The wounds were dressed separately. Two special nurses were detailed to the care of this case, whose duty it was to remove the lower dressing every hour during the day and every two hours at night, and with a pledget of sterile gauze to suck up all the fluid which would accumulate in the pelvis, introduce a dry piece of gauze into the glass tube and apply fresh sterile dressings—the procedure to be carried out with gloved hands and under the strictest aseptic precautions.

Considerable shock followed the operation and the patient was carried through the night only by the most energetic stimulation. The following day, however, she rallied somewhat but seemed exhausted, and although the pulse and temperature was not elevated she seemed seriously ill. There was practically no secretion of urine, and she died two days later in a condition of typical uremic coma.

Case II.—Operated upon at the City Hospital about the same time. A woman, forty-eight years of age, thin, anemic, and weakened by prolonged illness and dissipation. History of alcoholism and other vices for many years. Duration of ascites, two to three months. The operative procedure was practically the same as in the first instance, with the exception that chloroform was used instead of ether. The operation in this instance was somewhat prolonged, owing to difficulty in siphoning out the large amount of fluid from the pelvis, and also from the fact that in rubbing the parietal peritoneum and the surfaces of the liver and spleen there was an abundant oozing of blood which necessitated a good deal of subsequent sponging. All this delayed the operation, and the patient, having lost a considerable quantity of blood, collapsed on the table. She recovered, however, under vigorous hypodermic and rectal stimulation, only to collapse again after her return to the ward. From this she did not rally. She died within the next twenty-four hours.

Case III.—An Italian man, about forty years of age, who had been only moderately alcoholic and without history of syphilis, was admitted to the City Hospital in the winter of 1900. His general condition was fair; there was no albuminuria, but the abdomen was greatly distended. He had not been tapped, and was thought to be a favorable subject for operation. Chloroform was employed and the same procedure carried out as in the previous cases.

He bore the operation well and recovered nicely from the anesthetic. The following day his condition seemed very satisfactory; the pulse was of good quality and there was only a slight elevation of temperature. He seemed bright and cheerful. This continued for three days, when he began to vomit and complained of pain in the abdomen and general feelings of illness. The temperature rose. There was tenderness over the entire abdomen with slight distention and muscular rigidity. The bowels moved slightly as the result of enemata, but no cathartics were retained. The patient became delirious, the urine scanty and albuminous, and he died at the end of five days of peritoneal sepsis.

Case IV.—That of a man, about forty years of age, who was admitted to the City Hospital in January, 1901. He had a cough and had been feeling ill for several months, and of late had noted a gradual enlargement of the abdomen. There was an evening rise in temperature and an occasional night sweat. Examination revealed the presence of a tuberculous process in the right apex and a marked distention of the abdomen which precluded the possibility of obtaining any data as to the size of the liver and spleen. His case was regarded as one of tuberculous peritonitis and an operation proposed. He readily consented as he was failing rapidly in flesh and strength.

Under chloroform anesthesia an incision was made in the median line of the abdomen, when it was quickly seen that the case was one of cirrhotic ascites. The liver was small, hard and nodular, and the spleen enormously enlarged. As he did not bear the anesthesia well, the fluid was quickly evacuated, the upper surface of the liver and the adjacent parietal omentum were quickly rubbed with gauze, and the omentum

stitched to the anterior abdominal wall, which was tightly closed. The operation required only about ten minutes, and the patient recovered quickly from the anesthetic; there was no vomiting and no shock. The following day he expressed himself as greatly relieved. The wound healed kindly; there was no rise of temperature or other untoward symptoms. The fluid quickly reaccumulaed and he was tapped at the end of three weeks, again six weeks later. The appetite improved; he gained strength, and, although the cough was still troublesome, his abdominal condition was greatly improved. He was discharged in March.

Case V.—L. P., aged thirty years, native of Porto Rico, was admitted to the Private Patients' Pavilion of Roosevelt Hospital November 9th. No history of alcohol or syphilis could be obtained. His illness began about one year ago with an attack of dysentery. This was subacute from the first and gradully passed into a state of chronic colitis which has since continued. During the two months prior to his admission he had noticed a gradual enlargement of the abdomen and progressive emaciation. Weight 90 pounds.

Examination: Heart and lungs negative; abdomen greatly distended with fluid; no liver dulness could be made out and the spleen was not palpable. Examination of the rectum by sigmoidoscope revealed the presence of three large superficial ulcers in the lower six inches of the rectum. Temperature normal, pulse between 90 and 100. This case was also regarded as one of tuberculous peritonitis.

Under chloroform anesthesia an incision was made in the median line and the abdomen freely opened. There were no evidences of a tuberculous process in the peritoneum, which seemed to be quite normal in appearance; the sigmoid and rectum were greatly thickened and a number of glands were palpable in the mesentery. The liver was small, hard and nodular, and adherent to the under surface of the diaphragm. The spleen was enormously enlarged and its outer surface attached to the parietal peritoneum by dense adhesions. The omentum was stitched to the anterior abdominal wall and the incision tightly closed. Duration of operation, less than fifteen minutes. No shock followed. The temperature remained below 100° F. for one week, but the fluid reaccumulated so rapidly that the lower angle of the incision was opened and a tube introduced. This was followed by peritonitis and death.

It will thus be seen that all of these cases were true examples of ascites due to cirrhosis of the liver. Careful inspection and palpation at the time of operation in each showed a small liver, large spleen, and no evidence whatever of perihepatitis, chronic or tuberculous peritonitis. All were greatly distended with fluid and apparently in the last stages of toxemia from the disease. All but one had marked evidences of nephritis. One died of uremia, due to my mistake in using ether for anesthesia in a patient with marked evidence of nephritis; one from shock, due probably to faulty technic resulting in too long an exposure on the operating table; the third died from septic peritonitis, due in all probability to faulty technic in managing the drainage subsequent to operation.

The fourth case, although the most unfavorable of all, recovered from the operation without an untoward symptom, for the following reasons: Only a very small amount of chloroform was used, the operation was completed in about ten minutes, and no permanent drainage was employed, removal of the fluid being accomplished by subsequent tappings.

The fifth case did well for one week, showing no fever or signs of peritonitis. Symptoms of bronchopneumonia and later other evidences of general sepsis including a peritonitis, followed the subsequent introduction of a drainage-tube.

I desire to say in conclusion that, in reviewing the statistics furnished by this table, it will be seen that at least six cases have been cured of ascites by this procedure and have remained well for a period of two years or more; six others have been relieved of this symptom for from two to six months, but have died, either without a return of the ascites, or have not been under observation long enough to demonstrate that the cure is permanent. Another case, that of a patient suffering from hemorrhages from the alimentary canal, was promptly cured by this operation, and a number of others have been materially improved. Thirty-eight have recovered from the operation, and, when we consider that in the great majority of instances these patients were in the last stages of an incurable disease, and if we are to accept the statements of White and Thompson, within a few weeks of an inevitable death, this fact should, I think, encourage our medical friends to suggest the operation at an earlier and more favorable stage of the disease. If this is done, I firmly believe that later statistics will show a substantial improvement over those I am able at this time to present.

ON THE ETIOLOGY OF CIRRHOSIS OF THE LIVER.[1]

BY JAMES K. CROOK, M.D.,
OF NEW YORK.

As Dr. J. C. Wilson well said in his remarks before this Academy several weeks since, no definition can be framed which will include, both pathologically and clinically, all forms of so-called cirrhosis of the liver. A careful examination of the literature of hepatic disorders will show that only three distinct primary varieties of the disease have gained anything like a fixed or unequivocal position in medical terminology. These are (1) venous or atrophic cirrhosis, the original cirrhosis of Laennec; (2) hypertrophic cirrhosis, *maladie de Hanot*, and (3) biliary cirrhosis. A proliferation of the connective-tissue

[1] Read before the Section on General Medicine of the New York Academy of Medicine, Dec. 17, 1901.

stroma of the organ constitutes the one underlying anatomicopathological process common to all varieties. This new tissue may never reach the stage of cicatricial contraction, but remain always in a condition of proliferation, the liver thus continuing in a state of hypertrophy until the termination of the case. For the purposes of this paper only these three important forms of cirrhosis, upon the occurrence of which pathologists are generally agreed, will be considered.

Venous or Atrophic Cirrhosis.—This is by far the most common form of chronic interstitial hepatitis. Many writers describe no other. It is the form of the disease always implied when no further distinguishing designation is used. The causes of venous cirrhosis may be classified as predisposing and determining, of which the latter are by far the most important, the predisposing influences being merely those which facilitate the operation of the actual exciting causes. According to Giovanni of Padua predisposition may be said to consist in an excessive morbidity of the lymph-corpuscles which enter into the structure of the gland. Age and sex may be ranked as occupying positions of prime importance among the predisposing factors. In an analysis by the writer of 4,737 deaths from cirrhosis of the liver reported to the New York Health Board during the eleven years from 1889 to 1899, inclusive, the ages of the decedents were as follows: Under one year of age, 9; total under five years of age, 11; five to ten, 11; ten to fifteen, 9; fifteen to twenty-five, 553; twenty-five to thirty-five, 1,061; thirty-five to forty-five, 1,196; forty-five to fifty-five, 959; fifty-five to sixty-five, 560; sixty-five to seventy-five, 146; seventy-five to eighty-five, 14. It will be observed that the period from thirty-five to forty-five shows the largest number of victims of cirrhosis, while that between twenty-five and thirty-five is a good second, and from forty-five to fifty-five not far in the rear. This accords very closely with facts already well known to clinical observers. Notwithstanding Virchow's report of an autopsy in a congenital case, some writers have doubted the existence of the disease in infancy, but the presence in this list of 9 cases under one year of age, with a total of 11 under five, shows beyond dispute that cirrhosis of the liver may occur at an early period of life. With one exception all of the deaths in infants prior to one year of age were of males. However, a very interesting case of a girl baby, aged sixteen months, who apparently recovered, was reported by Dr. R. Abrahams of this city about two years ago. The case, with photographs, was presented to the New York County Medical Association (*Medical Record*, Jan. 6, 1900). Of the patients in the foregoing list 2,980, or 62.28 per cent., were males, and 1,757, or 37.77 per cent., were females. Of 37 cases treated at the Roosevelt Hospital in 1899 and 1900, notes of which were furnished to the writer by Dr. W. P. Millspaugh, house physician, 27 were males while only 10 were females. These figures go to show that middle-aged males from thirty-five to fifty-five furnish by far the greater proportion of victims of cirrhosis.

A question of interest relates to the nationality of persons dying of hepatic disorders. In the Health-Board publications cases of cirrhosis and hepatitis are grouped together in the tables referring to nativity. The writer has analyzed the returns for the nine years from 1889 to 1897, inclusive, the reports for 1898 and 1899 not covering this subject. During these nine years the nativities of cases from the five principal nationalities contributing to the list of deaths from cirrhosis and hepatitis were as follows: United States, 1,112; Ireland, 1,063; Germany, 774; England, 121; Italy, 98—a total of 4,168. As shown by the figures 1,112, or slightly more than 26 per cent., were native-born, while 3,056, or a little more than 73 per cent., were of foreign birth. The addition of natives of all other foreign countries contributing to these deaths would considerably increase the disparity between native-born and foreign subjects. These figures go to show that the foreign-born population of this city are vastly more liable to liver complaints than those who are native. Of the alien population the Irish would appear to furnish a somewhat greater proportion of victims to hepatic maladies than the natives of any other country, with Germany not far behind. No statistics relating to occupation are furnished by Health-Board publications. Of the Roosevelt Hospital cases just cited there were but one bartender and one saloonkeeper. Seven of the cases were ordinary laborers, while the remainder were scattered among various occupations. The observations of many eminent writers substantially agree, however, that persons pursuing sedentary occupation are much more liable to cirrhosis, as well as to other forms of hepatic disease, than those whose vocations keep them actively employed in the open air.

Among the exciting or determining causes of cirrhosis of the liver the *habitual imbibition of alcoholic stimulants*, especially strong spirits, such as whiskey, gin, and brandy, takes first rank. Of the 37 cases at Roosevelt Hospital, 29 presented alcoholic histories. Of 17 patients under the writer's own observation, all save two had been more or less addicted to the use of ardent spirits, usually in various forms. It must not be inferred, however, that the milder malt beverages consumed too largely of late years are innocuous in this direction. The statistics of the New York Health Board already referred to indicate that our beer-drinking German fellow-citizens supply almost as large a proportion of fatal cases of this disease as do those from Ireland who are popularly credited with being partial to more potent fluids. A German brewer, under the writer's care, who died a few months since of a typical hepatic cirrhosis after more than a dozen tappings, had consumed large quantities of beer daily, to the entire exclusion of strong spirits, for many years prior to his illness. Alcohol appears to have an elective affinity for the liver. Giof-

fredi (quoted by Semmola, Twentieth Century Practice) observed that if a cat were poisoned by alcohol administered subcutaneously, a third of the injected fluid would be found in the liver, a fifth only in the brain, a less amount in the kidneys and lungs, and a mere trace in the muscles and blood. If chronic poisoning be produced in an animal, alcohol will be found in the liver many days after its suspension and after its total disappearance from the other organs and from the blood. Lancereaux maintains that the *vin ordinaire* of France is a common cause in that country. Of 210 cases he found that in 68 cases this disease could be traced to no other cause except excess in this wine. Some writers believe that the influence of alcohol is wrought upon the liver by first producing a gastro-intestinal catarrh and that the resulting fermentative products of meat-digestion being absorbed and conveyed to the liver, gradually set up the morbid changes which eventuate in this disease. However this may be, clinical observers everywhere are agreed that the habitual use or abuse of alcohol is responsible for the vast majority of cases of chronic interstitial hepatitis in all civilized countries. Murchison claims never to have seen a case due to any other cause. In this connection it may be stated that a most dangerous practice consists in the ingestion of alcoholic beverages when the stomach is comparatively empty, for example, before meals and during the hour before retiring. Active exercise while drinking tends to diminish to some extent the liability to cirrhosis, as well as to other diseases, by promoting the speedy combustion or elimination of the poison, thus reducing the toxicity of the fluids and plasma. The ingestion of food also greatly modifies the injurious action of this substance upon the liver.

Syphilis has long been credited with an important influence in the causation of hepatic cirrhosis, Virchow having been one of the first to illuminate the subject of visceral syphilis and to demonstrate the occurrence of sclerosis of the liver from syphilitic infection (*Virchow's Archiv*, Vol. XV., p. 281. *Vide* also Lancereaux, "A Treatise on Syphilis," Syd. Soc. Edition). Of the cases above cited at Roosevelt Hospital, 3 gave syphilitic histories. The difficulty of obtaining information relating to the past occurrence of this disease is, however, well known. It is no doubt in not a few instances associated with alcoholic excess in the production of the trouble.

Malaria is credited by most writers with a causative influence in cirrhosis of the liver. Italian physicians especially, who see much malaria, believe it to possess an important etiological relation to cirrhosis. Osler (Practice of Medicine, 1901), however, states that in an extensive experience with malaria in the wards of the Johns Hopkins Hospital during the last nine years not a single case of cirrhosis due to this cause was seen. It is at any rate highly probable that the repeated attacks of hepatic congestion which mark the course of malaria at least strongly predispose the interstitial structure of the organ to inflammation.

Certain other *infectious diseases,* notably *typhoid fever,* have of late come to be regarded as causes of cirrhosis. The researches of Frerichs, Liebermeister, Cornil and Ranvier, Hanot and others, show that the liver is profoundly involved in the morbid changes of typhoid. The pathogenic mechanism would appear to be a double one relating both to the direct action of the bacillus and to the effects of the toxin. It is undoubtedly true that cases of cirrhosis in which all other causative influences are absent are met with dating from an attack of typhoid fever. Scarlatina, measles, cholera, smallpox and yellow fever have also been mentioned as standing in an etiological relation.

Overeating and, especially, *excessive indulgence in highly-spiced foods* may lay the foundation for hepatic cirrhosis. It is stated that the disease is very common in certain districts of India where the use of much spice is prevalent. It cannot be doubted that the liver readily reacts to the absorption of certain irritating food-products from the gastro-intestinal canal. Some of these might very reasonably be supposed to be capable of giving rise to connective-tissue inflammation. The cause of this process in the liver is probably only an exaggeration of its normal function, excited either by an abnormal stimulus or by an excessively increased physiological action (Semmola).

Certain mineral poisons, such as antimony, arsenic, and notably lead and phosphorus, have the power to set up irritative hyperplasia of the connective tissue of the liver. These metals accumulate in the organ in preparation for elimination. Lead, according to Potain, produces a marked sclerotic action on the liver, and Lafitte was able to excite true cirrhosis in rabbits by the continued administration of salts of lead. Lancereaux observed the disease among copper-smelters who were absolutely temperate.

It has been recently claimed by Von Kahlden (*Münch. med. Woch.*, Oct. 5, 1897) that cases of *acute yellow atrophy* of the liver which are not rapidly fatal develop into typical examples of cirrhosis. Marchand found that the liver of a woman who had six months previously suffered from an attack of acute yellow atrophy showed both macroscopically and microscopically a picture very closely resembling cirrhosis. Stroebe reports a similar case, while the case reported by Von Kahlden presents a third example of cirrhosis developing from acute yellow atrophy. If the views of Von Kahlden are borne out by further investigation, the causes of acute atrophy may also be regarded as indirectly productive of cirrhosis.

Among other causes of hepatic cirrhosis mentioned by various writers may be mentioned tuberculosis, cardiac disease, malignant growths, diabetes, ptomain-poisoning, chronic poisoning from sulphuric ether, inherited tendency, fright,

and traumatism. It will be observed that most of these latter causes produce secondary cirrhosis; the others are probably of little importance.

Hypertrophic Cirrhosis, Maladie de Hanot.—This form of cirrhosis, first accurately described by Hanot in 1875, is prominently mentioned by French writers, but appears to have attracted little attention elsewhere. In this affection the liver is uniformly enlarged and smooth, moderately granular on the surface and indurated. No data are offered to show how it can be distinguished during life from the hypertrophic liver of ordinary venous cirrhosis. It differs from that variety of the disease, however, in the tendency of the liver to remain enlarged. Sclerosis and contraction of the organ do not occur even in long-standing cases. The etiological factors appear to be quite similar to those of Laennec's cirrhosis. A greater proportion of cases, however, occur in early adult life.

Biliary Cirrhosis.—This form of cirrhosis consists fundamentally in a primary affection of the biliary reticulum, more especially in an angiocholitis or a peri-angiocholitis of the bile-ducts of small and medium caliber. The first result is a stasis of the biliary circulation followed by congestion and leading ultimately to permanent enlargement of the organ without tendency to sclerosis. It seems highly probable that the immediate cause of the trouble is an upward extension of some pathogenic influence through the biliary system. This theory has been advocated by Charcot, Goubault, and Chauffard, but it has not been definitely proved. The causal relations of this form of cirrhosis are still largely problematical. It is most frequently seen in young males of twenty to twenty-five and is in many cases alcoholic, but this influence is often absent.

ON THE TREATMENT OF THE ALCOHOLIC CIRRHOSES OF THE LIVER.[1]

BY GEORGE M. CONVERSE, M.D.,
OF NEW YORK.

Treatment, when it is not empirical, must come from as perfect a knowledge as we can obtain of the condition to be treated.

Until a few years ago the atrophic cirrhosis of Laennec and the hypertrophic alcoholic cirrhosis were attributed to the direct action on the liver of alcohol in its different forms. While there is no question that alcohol may so act directly as shown by the unimpeachable experiments of Mertens, who produced cirrhosis in animals by the inhalation of alcohol, later researches show that alcohol acts locally on the gastro-intestinal tract, causing a catarrhal inflammation, denuding the mucous membrane of its protective epithelium and thus facilitating the entrance of toxic substances into the portal system. These toxic substances are numerous; they result from incomplete and faulty elaboration of food, as toxic albuminoids or toxipeptones, or from fermentations and putrefaction of the intestinal contents producing various toxins and ptomains.

Meanwhile the study of the functions of the liver has made great advances; in addition to the biliary and glycogenic functions, the formation of urea, of uric acid, the elaboration of fats, the researches of Bouchard have shown that the hepatic cell fixes many mineral poisons and arrests and modifies most alkaloids, ptomains and bacterial toxins.

Again, in the case of the alcoholic cirrhoses it was formerly taken for granted that, cirrhosis having occurred, there was nothing to be done but to remove the ascitic fluid when necessary and otherwise to make the patient as comfortable as possible. Now we know, from a better, though still imperfect knowledge of the disease, that in its earlier stages, at least, much may be done toward a relative cure. The adult cicatricial connective tissue cannot indeed be removed, but, as Hanot expressed it, "While it is the presence of this connective tissue that confirms the diagnosis, it is the condition of the hepatic cell that indicates the prognosis." From these views as to the etiology of the alcoholic cirrhoses it is evident that the earlier the treatment is instituted the greater will be the chances of success; therefore the question of early diagnosis is of paramount importance. It is often said that cirrhotics come to the physician when it is too late to do much for them; this may be true of hospital patients. But these same patients have been seen before; they have been seen on the occasion of some trivial gastro-intestinal disturbance or acute alcoholism, etc.

Of 995 men whom I have examined in Dr. Dow's rooms at the Vanderbilt Clinic, 32 had large livers with clear alcoholic history. This number does *not* include those livers enlarged from active or passive congestion nor from tuberculosis or malaria.

There was one solitary case of classic atrophic cirrhosis of Laennec. Of the 32 cases, two only were advanced cases of hypertrophic alcoholic cirrhosis; 16 presented symptoms that would lead to the investigation of the liver, mostly gastro-intestinal symptoms of alcoholism, and 14 came for various pains and aches having no relation to that organ. If these cases with clear alcoholic histories, and after the elimination mentioned, were not cases of alcoholic hypertrophic cirrhosis in the *early* stage, what could they have been?

The indications for the treatment are as clear and logical as they can be. Since alcohol is the chief agent in the production of those conditions of the digestive tract necessary to the development of cirrhosis, it must be entirely suppressed. Since the gastro-intestinal epithelium is more or less injured, a diet must be given which will cause least irritation and be as little toxic as possible. This diet is milk and all authors agree that, to be effective, it must be exclusive.

Milk is a complete food which is easily digested and easily absorbed, and, as was shown some years ago by Gilbert and Domenici, is of

[1] Read before the Academy of Medicine, Dec. 17, 1901.

powerful assistance in diminishing intestinal sepsis, for, after five days of absolute milk diet these authors found that the number of microbes contained in the feces was 70 times smaller than before its use. This is at first surprising, since milk is an excellent culture-medium, especially for the colon bacillus. The reasons they ascribe for the fact are multiple: (1) The facile digestibility of milk; (2) the almost complete absorption; (3) the feeble nutritive power of the residue; (4) the chemical reactions occurring during its stay in the stomach. The quantity to be taken should be from three to four liters daily; more than this may cause stasis and fermentation; less would result in emaciation and loss of strength. The patient may take a half liter every three and a half hours or 250 grams every two hours; he should begin by taking one liter a day and increase a half liter each day, for it is rare that the patient can take the three liters at the start. Some patients enjoy the benefit of this milk diet for a short time only, and then develop such a dislike for it that they cannot bear the sight of it. This disgust is often induced by the fermentation of some of the milk that remains in the mouth and may be prevented by washing the mouth with Vichy after each one of the meals.

The diet should be continued until the gastro-intestinal symptoms and the congestion of the liver that are frequently present at the beginning of treatment have subsided. In early and simple cases a week or two may be sufficient; in more advanced cases it should be continued for from two to four months. In any case, it is gradually relaxed in favor of eggs, vegetables, etc., meat being returned to last of all. At the beginning of treatment, to clear the intestine of its toxic contents and at the same time to aid in reducing the congestion of the liver, a purgative is given and later mild laxatives at intervals. It is unnecessary to add that the patient should take advantage of rest, open air, moderate hydrotherapy, and lead as careful a life as his financial situation and occupation will permit.

In the moderate cases of cirrhosis before ascites these hygienic measures may be sufficient. Then we must take into account the process of the regeneration of the hepatic cells. This subject was first broached by Tizzoni in 1883, by Canalis in 1886 on the subject of the healing of wounds of the liver. In 1891 Ponfick and Von Meister of Berlin demonstrated the regeneration after the removal of one-quarter and even one-half of the liver in rabbits. It has been demonstrated in man, notably in a case of alcoholic hypertrophic cirrhosis of Dujardin-Beaumetz of Paris, in which the patient, after having been relatively cured of his cirrhosis for over two years, died in forty-eight hours of an acute lobar pneumonia; and, again, by Hanot in a case of biliary hypertrophic cirrhosis in which there were found many normal cells, others hypertrophied, others in full karyokinesis. It is also supported by clinical evidence, for Surmont finds a diminution of toxicity of the urine in five cases of hypertrophic cirrhosis examined, while the toxicity is increased in cases of atrophic cirrhosis in which the glandular element is almost totally destroyed.

When ascites develops, it is all important to differentiate between the atrophic and the hypertrophic forms of alcoholic cirrhosis. In the atrophic variety there is menace at once from the circulatory obstruction and from the glandular destruction. Hale White points out that the average duration of life after the appearance of ascites is eight weeks. Nevertheless, the treatment should be pursued on the same lines as previously stated, being supplemented by paracentesis and the judicious use of purgatives and diuretics, for the average does not speak for the individual case. In a recent thesis Willemin mentions sixteen cases of atrophic cirrhosis that were improved for periods varying from several months to several years.

Simply to mention the fact: Spillman has tried hepatic opotherapy in five cases of atrophic cirrhosis with encouraging results, for the treatment caused an increase in the amount of urine with parallel increase in urea, phosphoric acid, and an absence of albumin and urobilin. The same treatment had no influence on two cases of Hanot's biliary hypertrophic cirrhosis.

The general treatment is again the same in hypertrophic cirrhosis after the development of ascites. Its success, as H. Campbell Thomson indicates in a paper that has been referred to here, will depend largely on the nature of the ascites. If the accumulation of fluid is due to the mechanical obstruction in the portal system, it indicates an advanced stage of cirrhosis and frequent tappings will probably only precipitate the end. Such a fluid is pale, non-fibrinous, contains but little albumin and but few cells, and leaves a solid residue of about 2 per cent.

If the ascites be due mostly to the coexistence of a perihepatitis and chronic peritonitis, complete rest, together with the milk diet and removal of the fluid, may do much for the patient. This ascitic fluid is fibrinous, albuminous, rich in blood-cells and contains a residue of about 4 per cent.

Our knowledge of the intimate causation of ascites is very meager and such divisions are apt to be too schematic, for the same irritating sclerogenous cause is at work both on the portal system and on the finer vessels of the peritoneum. However this be, over two-thirds of the reported cases of relative cure of cirrhosis with ascites are of the hypertrophic variety. Many of them read like the following case mentioned by Chauffard in an article on the "Clinical Forms of Cirrhosis," read at the Congress of Moscow.

"The patient, a chronic alcoholic of many years' standing, entered the hospital in January with a well-marked hypertrophic cirrhosis and considerable ascites. From January to May he was tapped five times, 54 liters of fluid being removed. His general condition was bad with marked emaciation. At the end of May the ascites ceased and did not reappear. The patient

soon returned to ordinary diet, gained 13 kilos in weight and became quite as strong and able as before his illness. For over a year after this and up to the time of writing the patient had remained quite well, although some alimentary glycosuria showed that the liver had not recovered its functional integrity."

I have omitted symptomatic treatment and also the surgical side of the subject in the above considerations on the alcoholic cirrhoses. The first is, as Musser says, common property; the second is in itself a large subject.

ON THE DIAGNOSIS OF CIRRHOSIS OF THE LIVER.[1]

BY J. C. WILSON, M.D.,
OF PHILADELPHIA.

The diagnosis of well-defined cirrhosis of the liver, the terminal condition, is usually a simple matter. Whether it be the atrophic form of Laennec or the hypertrophic form of Hanot, the symptom-complex in most of the cases is characteristic. In the former the pinched face with its distended venules and muddy or subicteroid hue—*facies hepatica,* the spare chest and thin arms, the distended belly with its conspicuous superficial veins and the diminished area of liver dulness, leave no doubt of the nature of the malady. In the latter the jaundice, the fairly well-preserved nutrition, the big liver without ascites, and occasional irregular fever, render the diagnosis equally clear. The two conditions are clinically distinct because they are the manifestations of essentially different pathological lesions. The one thing that these lesions have in common is an overgrowth of the interstitial connective tissue of the liver. It might be said that they have nothing in common clinically save that they are diseases of the liver. Yet they are described respectively as the atrophic form and the hypertrophic form of the same affection, hepatic cirrhosis. It is of interest to investigate the etymological significance of this unfortunate word "cirrhosis," originally selected by Laennec to describe an anatomical peculiarity of the contracted liver far from constant, and subsequently applied to changes in other viscera attended by an overgrowth of connective tissue, so that there have been those who have spoken of cirrhosis of the kidney, cirrhosis of the lungs and the like. The word is derived from the Greek κιρρος, tawny or orange-yellow, the color of the liver substance in some of the cases. It has nothing whatever to do, save by a remote and misleading association, with the sclerotic changes due to hyperplasia of connective tissue stroma.

Vaughn in a recent study of the subject[1] concludes that so-called atrophic and hypertrophic cirrhosis are not different forms of the same disease but wholly different diseases. He states that the former is known as atrophic cirrhosis because from its earliest possible recognition the liver is less than normal in size; while the hypertrophic is known as such because at every stage of the disease the liver is larger than normal; that the atrophic is known as venous cirrhosis because of the early and constant involvement of the intrahepatic branches of the portal vein, the hypertrophic as biliary cirrhosis because of the early appearance and constancy of icterus; that in atrophic cirrhosis the primary destructive changes are in the hepatic cells, while in hypertrophic cirrhosis the epithelium of the gall-ducts is the site of the primary involvement; that the former might be known as toxic, the latter as infective cirrhosis. These are practically the views of most of the later systematic writers upon the subject, and in particular Quincke, in Nothnagel, and Semmola and Gioffredi in the Twentieth Century Practice.

This clear-cut classification, while in some respects convenient and while it provides categories for well-marked cases of widely different morbid conditions, by no means meets the requirements of all the cases and does not appear to be wholly justified upon etiological, anatomical or clinical grounds. There are cases of atrophic cirrhosis in the causation of which alcohol plays no part, and cases of hypertrophic cirrhosis in hard drinkers. My clinical experience leads me to believe that alcohol is a very common cause of this form of cirrhosis.

Cases of cirrhosis of the liver without jaundice and with the evidences of a high degree of portal obstruction in which the liver is normal in size or slightly enlarged are by no means rare. In addition to these there is the fatty cirrhosis common in beer-drinkers. There is a large group of cases in which the symptoms are neither those of the atrophic nor the hypertrophic form. These are designated mixed forms and are thought to be due to the coexistence of the two forms, the toxic and the infective, in the same individual. On the other hand, Hawkins of St. Thomas's Hospital, in the article on cirrhosis of the liver in Allbutt's System, expresses the opinion that the terms "atrophic" and "hypertrophic" are scarcely worth retaining. "The former," he observes, "has lost much of its fitness now that statistics show that the hob-nailed liver, to which it was originally applied, is not necessarily small, but is often in-

[1] Read before the Section on Medicine of the New York Academy of Medicine, Nov. 21, 1901.

[1] Journal Amer. Med. Assoc., Oct. 5, 1901.

creased both in size and weight," while "the phrase hypertrophic cirrhosis has become so complicated by the postulate of a biliary cirrhosis that its significance is vague and uncertain." Hawkins does not recognize a vascular or toxic form corresponding to the atrophic form of writers (Laennec's cirrhosis) and a biliary or infectious form (Hanot's cirrhosis), but states that "two forms of cirrhosis of the liver are induced by the excessive use of alcohol." These two forms are separated both in their morbid anatomy and in their clinical features. In the first, which is by far the more common, the newly-developed fibrous tissue is "multilobular," that is, it tends to surround large groups of hepatic lobules. This form is commonly associated with ascites but seldom with jaundice. In the second and less common form of *alcoholic cirrhosis* the new tissue is mostly developed around single lobules and the condition is properly described as "unilobular." There is little tendency to ascites, while jaundice is common.

In this connection may be mentioned Flexner's researches in regard to the new tissue in cirrhosis of the liver.[1] He found both the white fibrous tissue and the elastic tissue increased and the chief distinction between the histology of the atrophic and hypertrophic cirrhoses to depend upon the degree of extralobular growth and the freedom with which the lobules are invaded, and that "in hypertrophic cirrhosis there would appear to be less interlobular growth and an earlier and firmer intralobular growth."

The chief objection to the classification of the cirrhoses into atrophic, vascular, toxic, on the one hand, and hypertrophic, biliary, infective, on the other, is that it does not conform to the facts. An objection of minor importance is to be found in the failure to provide for the cardiac and syphilitic cirrhoses, cirrhosis due to pneumonoconiosis, that form arising from chronic obstruction of the bile-ducts, chronic perihepatitis—capsular cirrhosis—and other forms of minor importance.

The difficulties in the diagnosis of hepatic cirrhosis are not as in most other diseases accidental. They do not arise from the peculiarities of individual cases. They are essential and due to the fact that no definition can be framed that at once pathologically and clinically includes all the cases. This arises from Laennec's choice of a term descriptive of an inconstant phenomenon and without pathological significance. "Cirrhosis" is conspicuous among the nosological terms that hamper medicine and obstruct the progress of knowledge. If it could be erased from the list of diseases our conception of the various conditions to which it is applied would be greatly simplified. The one underlying lesion common to all of them is an overgrowth of the fibrous tissue of the liver. The term chronic interstitial hepatitis is at once descriptive of the anatomico-pathological condition and sufficiently comprehensive to include all the cases. Its more general use is to be desired.

[1] Trans. Assoc. of Amer. Physicians, Vol. XV., 1900.

The etiological relations of individual cases may be indicated by qualifying adjectives: (*a*) In general toxic, and in particular alcoholic, plumbic, gouty, diabetic, rachitic and the like. We must include here forms of interstitial hepatitis due to chronic phosphorus-poisoning and the abuse of condiments. The assumption that intestinal auto-intoxication gives rise to interstitial hepatitis requires confirmation. (*b*) In general infectious; in particular the specific febrile infections are occasionally followed by chronic interstitial hepatitis. Malaria produces similar changes and syphilis gives rise to three well-characterized forms, namely, diffuse syphilitic hepatitis, commonly congenital, gummata which undergo fibroid transformation, and an extensive perihepatitis with increase in connective tissue of the portal canals. (*c*) Mechanical irritation. The long-continued exposure to an atmosphere laden with dust-particles such as produce pneumonoconiosis, whether these be mineral or metallic, may also give rise to an inflammatory process in the connective tissue of the liver. (*d*) Congestive; the chronic hyperemia of the blood-vessels occurring in heart disease gives rise to an interstitial hepatitis—the cardiac liver. (*e*) Obstructive, the result of chronic obstruction in the bile-ducts.

Clinically not all forms of interstitial hepatitis can be recognized. The symptoms are often vague and referable to other organs, especially those of the gastro-intestinal tract. In many of the cases the condition during life can only be suspected, the morbid phenomena being those of the primary disorder. Direct physical signs are available for diagnosis only when there are definite changes in the size or contour of the liver. Hence, the cases of chronic interstitial hepatitis, whatever its course, must be arranged in three groups according as the liver is found upon physical exploration to be (*a*) of about the normal size, (*b*) atrophic, and (*c*) hypertrophic.

With the histological changes the diagnostician to whom the problem presents itself *intra vitam* has nothing to do.

a. Since there are no characteristic symptoms in many cases of chronic interstitial hepatitis, and since in many of the cases the liver remains of normal size throughout and is in all of normal size until the disease has made some progress, it follows that the diagnosis is impossible in a considerable proportion of the cases and in the earlier stages of all cases. The most that can be done is to assume that certain etiological factors, as alcoholism, malaria, valvular disease of the heart with failing compensation being operative, and more or less well-pronounced gastrohepatic symptoms present, the patient may have an interstitial hepatitis. The diagnosis under such circumstances must be purely an anatomical one, and this is frequently the case in the fatty form of interstitial hepatitis in which symptoms directly referable to the liver are often absent and not rarely in the multilobular form either with or without atrophy. In the lat-

ter instance the true nature of the malady may reveal itself in sudden copious hematemesis or in the peculiar toxemia caused by the entrance of portal blood which has not traversed the liver into the general circulation, to which Stockton has especially directed attention.[1]

When, however, there are decided changes in the size of the liver the state of affairs is wholly different. The interstitial hepatitis reveals itself not only in physical signs, but also in symptoms of significance.

b. The liver is diminished in size. A high degree of atrophy may occur provided the collateral circulation has been established without the development of ascites or other symptoms which attract the attention of the patient to the liver. As a general rule, however, the malnutrition, the enlargement of the spleen, the distended superficial abdominal veins and the increased girth caused by the ascites are diagnostic. It is of cardinal importance also to remember that all these phenomena can occur in an interstitial hepatitis in which the liver is not only atrophic but even somewhat enlarged. Under these circumstances jaundice is not usually present.

Adhesive pylephlebitis closely resembles the atrophic form of interstitial hepatitis. The etiological considerations and the rapidity with which the peritoneal effusion develops and reforms after tapping, as was shown in a case recently in my service in the Pennsylvania Hospital, are important in the differential diagnosis. It is said that thrombosis of the portal vein is followed by an atrophy of the liver, which renders the diagnosis difficult. In the cases that have come under my observation death has occurred in the course of a few weeks and the liver was of normal size.

c. The liver is increased in size. The hypertrophic form of chronic interstitial hepatitis—Hanot's disease—like the forms already considered, may present insuperable difficulties in diagnosis in its early stages. The liver may be as yet of normal size. The early icterus may resemble that of catarrhal jaundice—a resemblance heightened by its fluctuation or temporary disappearance and by the occurrence of fever. The recurrence or persistence of the jaundice, its intensity and the presence of bile in the stools are of diagnostic importance. When the disease is established the uniform enlargement of the liver, the splenic tumor, the deep and persistent jaundice and the occasional attacks of fever are diagnostic. The fever is of subcontinuous or remittent type and extends over periods of days or weeks. Chills and sweating are not common, as in the fever of impacted gall-stone—Charcot's or true hepatic fever.

The diagnosis of hepatic capsulitis—the capsular cirrhosis of authors—is usually attended by insuperable difficulties. The symptoms are those of the atrophic form of chronic interstitial nephritis. Jaundice is not usually present. The kidneys are granular. This condition may be associated with perisplenitis and proliferative peritonitis.

In conclusion it may be affirmed that:

1. The term cirrhosis is an unfortunate one. It has been applied to conditions wholly unlike etiologically, anatomically and clinically, which have, however, in common an overgrowth of the connective tissue of the liver.

2. The term chronic interstitial hepatitis is to be preferred.

3. Alcohol is by far the most common cause of interstitial hepatitis alike in the cases in which the liver is of normal size or slightly enlarged, in the atrophic form and in the hypertrophic form.

4. The symptoms of this condition are in many cases ill-defined and not rarely the liver is not changed in size or contour. The clinical diagnosis in a large proportion of the cases is therefore impossible.

5. In the presence of definite symptoms and of the signs of enlargement or diminution of the liver, that is to say, in terminal conditions, the diagnosis is commonly a simple matter.

CIRRHOSIS OF THE LIVER AS SEEN IN CHILDREN.

BY W. C. HOLLOPETER, A.M., M.D.,
OF PHILADELPHIA.

In presenting this very brief paper on cirrhosis as found in young life, I will preface my remarks with the statement that I shall limit myself entirely to answering the question in the affirmative, with some attention to its etiology and diagnosis. The subject is usually dismissed with a comparatively vague article in the text-books by American authors, or a compilation seems to be the order of their researches. English writers seem to have had more experience, evidently by reason of a long line of heredity and unfavorable environments, and they probably give about as clear an outline of the subject as is to be found in literature.

Cirrhosis has its analogy arteriosclerosis in early life and with this latter affection might be regarded as a rare condition. Liver diseases are, however, usually the results of secondary troubles and, as such, they require the element of time to produce them. Unfortunately adult age is reached oftentimes before the secondary results are discovered. Sclerotic blood-vessels are no longer an unusual feature in adolescence, and portal fibrosis is not so unusual as has been clinically demonstrated, especially when we consider heredity, environment and the neglect of personal hygiene among parents as well as among the children. The embarrassing point in all liver trouble in young life is that we so frequently forget the relative over-size of the organ, and to this fact is due the frequent error of regarding the organ as pathological when it is, in reality, normal, or, at best, functionally distended above its usual volume. Thus, septic jaundice frequently enlarges the organ, owing to pressure and enlargement in the bile-ducts by

swelling of the connective tissue around the branches of the portal vein in the liver. This form of enlargement is associated fortunately with a temperature and symptoms of apparent invasion which makes the diagnosis quite easy.

The progress of this form of trouble is somewhat slow, with many of the features of fibrosis, and it has been frequently so diagnosticated.

Cirrhosis of the liver in children and inflammation involving the fibrous tissues, capillaries, lymphatics or bile-ducts separately or combined, is no longer regarded as a rare disease, now that we have so vast a field for the collection of data; any one who has enjoyed a number of years of hospital experience, seeing many children, can so testify. Ten years ago it was taught that cirrhosis was one of the rarest diseases among children. Drs. West, Birch-Hirschfield and Henock call it absolutely rare. Dr. Palmer Howard, however, has collected more or less complete accounts of 63 cases occurring in children, and Dr. Marcus P. Tatfield, 93, reported during the past 50 years, which makes 156 cases, all told; so we are compelled to agree with Eustace Smith, a pioneer of the study of this disease in children, in the statement that there is reason to believe that hepatic cirrhosis is less uncommon with children than is generally taught.

The pathological division and subdivision of liver diseases have been confusing to clinicians and we will dismiss this portion briefly, confining ourselves strictly to the clinical picture of cirrhosis as seen in early life.

Interstitial hepatitis in infants is most probably syphilitic, of course inherited. I have never seen an exception to this rule. The stigmata in the inheritance is usually found on close investigation. In older children the disease may occur apparently without any other tissues being involved; yet it is the outgrowth of some systemic disorder. Alcoholism, the most frequent single cause, according to Dr. Dawson Williams, accounts for about one-sixth of all the cases in children. While this agent is so very destructive to adult livers, it cannot be so readily proven in childhood. It is not quite clear that "the sins of the fathers are visited upon the children." It is true, however, that among the users of alcohol, the young are indifferently cared for: irregular feeding, poor personal hygiene, making children cross and unhappy, necessarily to be quieted by gin, brandy and the various alcoholic anodynes to secure temporary comfort from the results of improper and irrational feeding. The amount of aromatic wines, cordials, essence of pepsin, gin, etc., systematically administered to infants by shiftless and ignorant parents to offset care and attention can never be known, except as we see the unfortunate results in the hospitals and dispensaries of our large cities. This factor in the production of cirrhotic livers in young children has never been sufficiently recognized and is no doubt the beginning of many of the wretched lives seen in dispensary and hospital work. It is not only found in the very poor, but in the underfed babies of the rich that are entrusted to careless or indifferent nurse-maids who are surreptitiously administering to their young charges gins and aromatic anodynes sufficient to secure the child's quietude, in order that their personal comfort may be attained. This is an evil that is rapidly growing, and needs wide recognition for its suppression.

General tuberculosis is sometimes accompanied by fibrosis of the liver, yet I am not quite sure to what degree; about one-third of the cases of hepatitis follow in the wake of acute infectious diseases, typhoid fever, measles and scarlet fever. I have seen one case which I thought was the sequel of whooping-cough. Dr. West mentions a box of six and Dr. Wettergren a boy of five suffering from interstitial hepatitis, both of whom were in the habit of drinking largely of coffee. Most of the cases of fibrosis of the liver in children are hypertrophic, except the alcoholic in the last stages. The organ is large, in color gray or orange-yellow, and finely granular. The large size of the liver is due to the fact that the hepatic cells do not atrophy nor does the fibrous growth retract. The symptoms of the two forms of hepatitis—the atrophic and hypertrophic—by reason of their different pathological conditions in the earlier stages cannot be clinically discriminated, and it is well for us to dismiss at once any efforts to do so that we may gain a proper conception of the trouble. The early picture of this condition is blurred by the ever-present evidence of the symptoms of indigestion, and this especially is impressive, as the disorder occurs among a class where personal hygiene is unknown or unrecognized. We will always find evidence of interference of nutrition chiefly affecting the portal circulation in hypertrophic fibrosis and the circulation of the biliary vessels in atrophic hepatitis; yet this characteristic cannot be seen early enough in many cases to be of especial value. The child will be a sufferer from the vague symptoms of indigestion for a long time, a veil that covers many errors. Restlessness at night for many months perhaps, flatulence, occasional vomiting, constipation alternating with diarrhea, evidence of dyspeptic diarrhea, with feverishness will be noticed; sallow skin, earthy in places, harsh and dry, elevated hair-follicles, with a putty-colored skin; soon come dark circles under the eye and loss of flesh, especially noticeable in the arms and legs. After this train of symptoms has existed for some months, improvement, alternating with many relapses, takes place. On closer scrutiny you will find the abdomen larger than usual and on palpation fluid will ofttimes be discovered. The first pronounced characteristic symptoms are, therefore, ascites, with wasted, waxy limbs, some edema ofttimes of the feet. The stigma of fine, dilated veins on cheek or nose or in the ear will ofttimes be a finger-board to our diagnosis. Larger veins are found on the abdomen, forming four or five large branches running

down from the xiphoid cartilage to the groin. These veins communicate above with the epigastric and internal mammary and below with the iliac and saphenous veins. The course of the blood is, therefore, from above downward. The dilatation may commence later than ascites and may continue long after it has ceased. Venous embarrassment is a certain evidence of portal obstruction. The stigma found on the face and ear and nose ofttimes is, of course, inherited, but it is also a fairly certain guide to the pathological changes going on within the child. The enlarged liver may be palpated, unless dropsy is extreme, and the enlarged spleen is better felt with the child on all-fours. The spleen is almost invariably disturbed in liver disorders and will be found to be somewhat beyond the normal size. The nose bleeds easily and occasionally hemorrhoids form or slight bleeding from the bowels is an associated symptom.

With this outline of cirrhotic liver in young children, I beg to append the brief histories of two that have been very recently under my personal observation. The one of alcoholic fibrosis is still under observation. The case is briefly, as follows:

Case I.—E., aged nine years; a healthy child, born of healthy parentage; was breast-fed up to six months of age, when the bottle-feeding was commenced. The grandfather is a sufferer from cirrhosis. The child being an only one received unusually careful attention from well-to-do patients, whose affection was so intense that it was ofttimes misplaced. Every whim was gratified and, unfortunately for the little patient, the grandparents' indulgence exceeded their wisdom; sweetmeats and various tastes of cordials were permitted from time to time, and at the beginning of the second year the first attack of catarrhal jaundice was ushered in, which continued more or less as an element of trouble for several months. This condition of gastric irritation was repeated from time to time in the last two or three years and is at present regarded as the almost constant feature of the child's trouble. The slightest irregularity in its dietary is bound to awaken some gastric distress, and if this is not promptly met the child drifts into a form of catarrhal jaundice with considerable irritation and wasting. These attacks have continued throughout the child's life up to the present time. We now find a liver considerably enlarged, with some ascites. The line of venous marking is very beautifully illustrated. The dilatation of the abdominal veins is as marked as in an advanced case of ovarian dropsy or chronic cirrhosis in the adult, with marking of the dilated veins in nose and face. The limbs are considerably wasted and the child's conjunctiva is muddy and slightly jaundiced; the tongue is pasty and the stomach rebellious. On palpation I found the liver down to the level of the umbilicus and quite large and tender. I have no doubt that we have in this case one of those chronic forms of hepatitis due to irregular and constant feeding, plus a great deal of the element of heredity that conspires to make this one of the earlier types of cirrhosis as found in adolescence. The symptoms are gradually but surely growing worse and associated with that physical decline is a striking change in the child's disposition; from a bright, lively, vivacious child she has become very sullen, given to fits of anger and sulking; and has lost, to a great extent, her desire for things childish and playful.

Case II.—Annie S., baby, admitted to my wards of the Philadelphia Hospital, December 1st, with the history of one week's illness which began with swelling of the legs and abdomen. This has since disappeared. She was an anemic, poorly-nourished baby of seven weeks, and weighed 8 pounds and 2 ounces. The face was covered with an eruption which was at first vesicular, then scaly. The hands, arms and legs were desquamating large areas of skin; the chest was covered with an eruption resembling urticaria, while the skin on the feet and legs was erythematous. The abdominal veins were large and distended, showing engorged portal circulation. The liver extended from the sixth interspace to three finger-breadths below the costal margin and from the ensiform cartilage to a line drawn to the angle of the scapula. The spleen was easily palpable, enlarged about twice its normal size. The heart-sounds were clear, regular, distinct. The blood examination microscopically showed blood dyscrasia marked. She nursed well, but in small quantities; temperature was hectic, varying from one to two degrees; stools were green. On the fourth day after admission the temperature was higher in the morning than in the evening; for the three days 98° to 103.6° F. No rigors were noticeable, nor did the child perspire. The child's face was then one raw surface, the superficial skin having peeled off. The skin of the buttocks and at certain places over the arms, legs, back, abdomen and chest had become vesicular, peeled off, leaving a raw, irritated surface. The child did not suffer much; cried only when dressed or handled; liver and spleen remained enlarged. On the sixth day the blisters had extended to and covered the greater part of the groin, buttocks and legs. The face was literally covered with blebs and was rather raw as the result of the bullæ bursting. Breath-sounds harsh, respiration accelerated, child did not sleep well, but had apparently no pain; seemed much weaker at night; temperature 104° F. Child died on the seventh day after admission.

Postmortem.—On inspection, liver was found to be 15 cm. by 10 cm. by 4½ cm. On the upper part of the anterior surface in the median line of the liver was a white patch, densely opaque in the center and shading out to the surrounding tissue. On incision, the opacity was found to extend inward about 2 mm.; probably a thickened capsule, otherwise no pathologic lesions were found. Microscopically fibrous changes were found in the ducts and the condition of true

cirrhotic change was found in the vessels and in the connective tissue surrounding the hepatic cells. The spleen was 8½ cm. by 4½ cm. by 2½ cm., enlarged 3 times its normal size. Capsule thickened. On section, no special pathological lesion was found. Liver weighed 230 grams; spleen, 45 grams. This was evidently a case of syphilitic fibrosis of the liver.

Recapitulation.—Briefly recapitulating, we may infer that cirrhosis of the liver in infants and adolescents is not so infrequent as clinicians infer, that cirrhosis in children can generally be relegated either to syphilitic or alcoholic types, with a very small percentage as sequelæ of the acute infectious diseases.

As a rule, the premonitory symptoms are disguised by a long train of gastro-intestinal irritation that renders an early diagnosis uncertain.

INTESTINAL OBSTRUCTION DUE TO GALL-STONES.[1]

BY LEWIS STEPHEN PILCHER, M.D.,
OF NEW YORK;
SURGEON TO THE METHODIST EPISCOPAL AND TO THE GERMAN HOSPITALS.

That a gall-stone, after having entered the intestinal tract, should by reason of its size become a cause of serious obstruction to the fecal current is a proposition that naturally might be greeted with skepticism, especially at this day when surgeons are frequently placing in the jejunum so large a foreign body as a medium-sized Murphy button with the confident expectation that after a few days it will appear at the anus, an expectation that is rarely disappointed. It may be remembered that as recently as 1898 there was reported to this Society by Dr. Elsner (Transactions Med. Soc. State of N. Y., 1898, p. 282) the case of a woman who passed by the anus two enormous gall-stones, the first one five and one-half inches in circumference and three inches in length, and the second one three inches in circumference and two inches long; an interval of about one year occurring between the appearance of the stones.

That so fortunate an ultimate result can not always be depended on must nevertheless be admitted. The statistics of Leichtenstern, given in Vol. VII. of Ziemssen's Cyclopædia of the Practice of Medicine, collected previous to 1875, are familiar to the present generation of readers. Among 1,541 instances of obstruction of the bowels from all causes collected by that writer, there were 41 which were due to gall-stones.

In the later statistics of Gibson (*Annals of Surgery*, 1900, XXXII., 486) such obstructions appear in still greater proportion. Among 1,000 operations for acute intestinal obstruction, compiled by that writer from the literature of recent years, in 40 instances the obstruction was due to the impaction of a large gall-stone within the bowel. In 1892 Kirmissen and Rochard (*Archives générales de Médecine*, February, 1892) were able to collect from all sources 105 cases of intestinal obstruction by gall-stones.

In my experience I have met with this condition but once. The account of this case is as follows: In August, 1898, a large well-nourished woman, about sixty years of age, was admitted to the Methodist Episcopal Hospital with acute intestinal obstruction. The symptoms had been developing with increasing intensity for two days. Previous to their inception she had supposed herself in good health; there had been no jaundice, nor other symptom to call attention to any lesion of the gall-passages. The attack had begun with pain in the umbilical region, followed by vomiting, and was regarded at first as a transient fit of indigestion. The vomiting, however, persisted and after twenty-four hours became fecal in character; the abdomen became tumid; the bowels were constipated. This was her condition when brought to the hospital.

Upon admission her general condition was good; the early appearance of the fecal vomiting suggested an obstruction in the nearer portion of the small intestine and the absence of shock and severe pain tended to eliminate the idea of any internal strangulation. As soon as the proper preparations could be made I opened the abdomen by a five-inch longitudinal incision in the linea alba, the incision beginning above the umbilicus and extending below it. Distended coils of small intestine presented in the wound. The systematic withdrawal of these through the wound upon the outside of the abdomen was begun, but after a very short time was arrested by the apparent adhesion of the loop that was being drawn upon in the depth of the abdominal cavity in the duodeno-jejunal fossa. The finger following down to the point of adhesion felt a hard mass in the intestine at the adherent point; the adhesions, which were recent and soft and not extensive, were readily separated and the loop containing the foreign body was brought to the surface. After the usual preparations for incising the bowel an opening was made into it at a little distance away through healthy tissue, through which the foreign body was removed. The intestinal incision was then sutured, the exposed loop was carefully cleansed and replaced within the abdominal cavity and the parietal incision was sutured except at its lower angle where an iodoform-gauze mesh was placed as a temporary drain extending down to the site of the intestinal suture. An uncomplicated recovery followed. I have frequently seen this woman since. She is in robust health.

The foreign body proved to be a large gall-stone, nearly spherical in shape, with an average diameter of about one inch and a circumference of three inches. Its size is not so great but one would suppose that it would readily have passed along the whole extent of the alimentary canal without producing any serious obstruction. The conditions which were revealed by the operation show that other causes than the mere physical blockade of the lumen of the intestine

[1] Read before the Medical Society of the State of New York, Oct. 15, 1901.

by the mass of the calculus contributed very materially to the final catastrophe. I would trace the sequence of these secondary causes in this order: The weight of the calculus was sufficient to prevent the free movements of the loop in which it was held; the mechanical irritation due to its prolonged retention at the most dependent point of this loop produced a circumscribed congestion of the underlying bowel-wall, favoring the transmission of infection and a resulting localized peritonitis which glued the loop, sharply bent upon itself into the depth of the duodenojejunal fossa, and thus added the condition of angulation of the bowel to whatever of obstruction the calculus had previously produced. The combination of the two conditions produced the complete obstruction, with the symptoms that led to operation.

It has occurred to me that this case is probably not exceptional, but is fairly typical of what must occur in many of the cases of intestinal obstruction from gall-stones. The conclusion seems to be a reasonable one that in such cases the final determining factor in the obstruction is not so much the bulk of the gall-stone as it is the secondary development of conditions at some point of the bowel-wall in the downward course of the calculus which lessen the contractile propulsive power of the bowel-wall. Such local paresis readily favors angulation and the progressive development of the symptoms of complete obstruction rapidly follows.

These stones enter the intestinal canal presumably by ulcerative perforation through the adherent walls of the gall-bladder and the duodenum.

In the literature of the subject it will be found that great diversity of opinion has existed as to the character and intensity of the symptoms which have attended the earlier evolution of these cases up to the time of the final attack of obstruction. That, as in the case of my patient, there should have been entire absence of any notable abdominal symptoms has not been unusual. Rarely do symptoms of obstruction arise at once upon the entrance of the stone into the cavity of the duodenum. Not until the lower portion of the small intestine is reached does the obstruction declare itself, as a rule. It is fair to ask why the stone should be arrested here if it has not been too large to pass along the higher portions of the intestinal tract. The dilatability of the intestine, the propulsive power of its muscular wall is not any less here than in the part already passed through. The thinner and less vascular coat of the ileum and the extreme mobility of its numerous coils render it, however, more prone to what I may call decubital irritation from the presence within it of a foreign body like a large gall-stone and the development of circumscribed peritonitis, with its attendant paresis and probable adhesions and possible acute angulation. I am inclined to assign therefore to "decubital irritation" the most important rôle in the causation of intestinal obstruction by gall-stones. I emphasize it in the present communication because its general presence and influence in the earlier course of these cases have not hitherto received that notice by writers upon this subject which they deserve, although the frequency with which necrosis of the intestinal wall and circumscribed peritonitis have been found in cases which have come late to operation, has been noted by observers.

The diagnosis of gall-stone as the cause of an intestinal obstruction must often be obscure and uncertain. This will necessarily be the case in those not infrequent instances in which the symptoms of obstruction declare themselves suddenly and without previous signs of a cholelithiasis. Most of the symptoms that attend the condition of gall-stone intestinal obstruction are at best suggestive rather than positive. The greater number of these cases occur in women over fifty years of age. The obstruction is in the small intestine and retroperistalsis is early induced, provoking copious vomiting that soon becomes fecal; yet without the signs of shock and early collapse that mark an internal strangulation. For the same reason excessive tympany does not develop. The obstruction may be incomplete and a chronicity or intermittence of the symptoms may mark the case. In a very considerable proportion of cases, over 50 per cent., according to Naunyn (*Klinik der Cholelithiasis*, Leipzig, 1892, p. 173), a spontaneous moving on of the blockading calculus is ultimately effected and recovery ensues without surgical interference.

All these symptoms, however, are quite as likely to be caused by an annular carcinoma and, with the exception of the intermittence or spontaneous relief of the symptoms, by internal hernias and constricting bands.

If in a given instance the physician could be positive that the case is one of gall-stone obstruction, he might be justified in adopting an expectant attitude. In the present state of intra-abdominal surgery, however, the onus of adopting such an attitude toward any case of intestinal obstruction has become a very serious one, since exploratory abdominal section *per se* has become established as a relatively safe procedure and since by such section alone can a positive diagnosis be made. The establishment of the diagnosis of the particular cause of any intestinal obstruction is, of course, in the line of scientific precision, and thoroughness and exactness of investigation to arrive at a conclusion are always to be employed before proceeding to the abdominal section, but it is not to be overlooked that this section is the most important means of diagnosis, while it at the same time opens the way for the application of the supreme means of relief.

Of the forty cases of operation for gall-stone obstruction gathered by Gibson twenty-one were fatal. The length of time that the symptoms of obstruction had existed and the general condition of the patient at the time she (three-fourths of the pa-

tients were women) was brought to the operating-table are unfortunately not given by Gibson for on these points must hinge considerations of the greatest importance. The tendency to death is generally by exhaustion and auto-intoxication; in some cases a general peritonitis develops and closes the case. Treves (Intestinal Obstruction, p. 329) gives the average duration of the final acute attack as seven days, the shortest period being four days, the longest fifteen days. It is obvious that if operative interference is to be attempted, the probabilities of success must steadily decrease with the lengthening of the time since the onset of the obstruction symptoms. The best results are only to be obtained by resorting to operation before the recuperative powers of the patient have become exhausted and while the local damage is still slight. As soon therefore as the symptoms of obstruction are positive, whether the presumption of a gall-stone as its cause is entertained or not, the surgeon is justified in opening the abdomen, first as a diagnostic —and secondly as a therapeutic procedure. The presumption that the cause of obstruction is a gall-stone should not induce the adoption of the policy of delay in the hope that the obstructing body would eventually pass, but such a presumption may rather stimulate to early operation, for it creates the expectation of encountering a condition, when once the abdomen is opened, which is readily and quickly amenable to simple surgical efforts.

Doubtless if this recommendation is followed some cases will be operated upon that would have recovered if they had been left alone; possibly some operative fatalities may also occur among these same cases; but the proportion of operative fatalities among patients unnecessarily operated upon will bear but an insignificant relation to the increased number of operative recoveries among patients who but for this early interference would have died as the result of gall-stone impaction.

PERCUSSION OF THE LOWER BORDER OF THE LIVER.

BY ALBERT ABRAMS, A.M., M.D.,
OF SAN FRANCISCO.

The value of regional hepatic percussion needs no expatiation. No one however skilled in percussion can gainsay the insurmountable difficulties which beset the clinician in his attempts to demarcate an organ which is immersed in an atmosphere of tympanitic sound, and the edge of which does not exceed one centimeter in thickness. Take into consideration the facts that the contiguous viscera, stomach and intestines, vary in their degree of inflation and in the character of their contents, and we have additional factors which modify the accuracy of our percussional results. Posture and the phases of respiration are likewise disturbing elements. A liver may be very much enlarged, yet percussion as ordinarily practised may give absolutely no evidence of enlargement, if examination is made in the recumbent posture. A good rule to follow is never to declare the liver to be enlarged unless it is palpable; but palpation may detect a liver which is dislocated though not necessarily enlarged; and, again, rigidity of the abdominal parietes may negative the value of palpation.

In my "Manual of Diagnosis" I have referred to two methods of determining the lower border of the liver. One method is that described by C. Verstraelen, which is based on the fact that the intensity of the heart tones is well preserved over the entire hepatic region; at the lower border of the liver, however, the tones are suddenly lost; and in this way the lower liver border is determined. The abdominal walls must be relaxed, otherwise they will conduct the heart tones. This method I consider imperfect, as it is never of value if the cardiac tones are weak. Another method which I advocated in the same book is as follows: The patient is placed in a position favoring the approximation of the liver to the abdominal walls. This position is the knee-elbow one, or, if this is impossible, the erect posture, the body being inclined forward. The edge of a large coin is then deeply embedded in the abdominal walls, and the free edge of the coin is percussed lightly and shifted gradually upward from the tympanitic area until dulness is elicited. If this dulness represents the liver border, then, in accordance with the fact that the liver undergoes respiratory dislocation, the line of dulness will be lower during inspiration and higher during the act of expiration. The essential object embodied in this method is to verify the correctness of the percussion by dislocation of the organ during respiration. The latter method is relatively inaccurate, as I have had occasion to observe by controlling the percussional results by palpation in numerous instances where the latter method was easy of attainment.

A simple maneuver for mapping out the lower liver border on the surface of the abdomen is as follows: The patient is instructed to incline his body backward as far as possible and, to relieve the tedium of the posture, the body is supported by means of the hands resting on the hips. If percussion, which must be light, is now attempted, the difficulty of determining the lower hepatic border is reduced to a minimum.

If we analyze the rationale of this maneuver we will find that it involves a simple law in physics, viz., that sound waves are best conducted by the medium in which they are produced. If the waves of sound are compelled to pass through media of different density, some of the waves will be lost by reflection and the sound becomes correspondingly enfeebled. Solid bodies conduct sound better than air. If percussion of the lower liver border is executed in the conventional manner, the percussion sound first passes through the relatively-dense abdominal musculature and then through the air-containing viscera before it reaches the liver. Theoretically at least, the percussion sound becomes enfeebled by the time it reaches the liver inasmuch as the high

pitch which reveals anything solid is dependent on the loudness of the percussion note, which in turn depends on the force exerted in percussion. We dare not employ a strong percussion sound in mapping out the lower hepatic border, for, by so doing, we set in vibration the air contained in the neighboring viscera and defeat the original object of our percussion, viz., the elicitation of a dull sound. In the posture suggested, we approximate the surface of the liver to the abdominal parietes, thus affording a like medium for the transmission of the percussion sound. When patients are compelled to assume a recumbent posture the same object may be achieved by directing them forcibly to contract the abdominal muscles during the time percussion is executed. The results by the latter maneuver, however, are less accurate, though relatively better than by the conventional method of percussion.

Percussion of the liver while the abdominal muscles are contracted is a valuable means of ascertaining sensitiveness of the liver. It is a better method than palpation, which only admits of testing the sensitiveness of the lower border of the liver. I am cognizant of the dictum of Frerichs, who directed attention to the fact that contraction of the abdominal muscles will frequently yield a dulness on percussion which is likely to be confounded with the dulness of the liver. This objection is to my mind purely theoretic. There is one condition, however, which demands consideration in percussion of the lower liver border and that is the presence of fecal concretions in the intestines contiguous to the liver border. The observation is undoubtedly correct that no one should rely on the results of liver percussion unless the bowels have been previously cleared by free purgation. This teaching applies with all cogency to the entire abdomen. Experience has taught me the following simple method of determining the presence of fecal matter: If by palpation or percussion we suspect the existence of fecal stasis—massage of the suspected area for a few seconds will dissipate the dull percussion sound, which will then be supplanted by a tympanitic percussion tone. It is therefore imperative, before determining the lower border of the liver by the maneuver already suggested, to massage that region for several seconds.

There are two additional facts which deserve mention: First, the patient must be cautioned to take no inspiration before contracting the abdominal muscles, for by so doing the liver will be dislocated downward; second, in practising percussion, the finger receiving the percussion blow must be firmly embedded in the abdominal wall; otherwise, the blow will not be directly transmitted to the liver.

Sir William MacCormac's Successor.—Dr. F. W. Pavy, F.R.S., has been elected to the office of president of the National Committee for Great Britain and Ireland of the Fourteenth International Congress of Medicine, to fill the place of the late Sir William MacCormac, who had enjoyed this honor for many years.

TUMORS OF THE LIVER.[1]

BY GEORGE RYERSON FOWLER, M.D.,
OF NEW YORK.

Neoplasms of the liver occurring as primary growths are very uncommon. They may spring from the epithelial structure, adenomata and carcinomata representing this type, or from the connective tissue, as represented by fibromata, fibro-neuromata, and sarcomata. Secondary carcinoma follows a primary growth in the stomach in about 25 per cent. of the cases.

Echinococcus Cysts.—The embryo of the tenia echinococcus gains access to the various organs of the body by means of the chyle through the thoracic duct and vascular system. The liver is particularly predisposed to the parasitic development, the embryo gaining access through the portal vein, where it forms the most common tumor of the liver, with the exception of carcinoma.

In typical cases a soft, fluctuating and insensitive tumor is found in the region of the liver, which rises and falls with the movements of the diaphragm, providing there are no adhesions to the abdominal wall. The so-called hydatid thrill of Santorini is a peculiar vibration supposed to be caused by movements of separate cysts ("daughter cysts") within the firm capsule of connective tissue which encloses the cyst proper. It is elicited by striking the tumor with the finger-tips, the other hand being placed upon the tumor at a distance. It is not always present. Jaundice is not a common symptom, and is only present when compression of the bile-ducts occurs. The chief symptoms of echinococcus cyst are a feeling of weight in the region of the tumor, and, if the tumor is large, there is some interference with respiration, as well as digestive disturbances from pressure upon the stomach and intestines. These cysts may reach enormous proportions and rupture occur. The rupture of the cyst may take place in the stomach or intestine, thus leading to a spontaneous cure. Rupture into the blood- or lymph-vessels may take place, particularly into the vena cava, and prove immediately fatal. Rupture into the peritoneal cavity may cause fatal peritonitis. If the patient survives this accident, an extensive development of cysts follows. Rupture into the pleura, lung, pericardium or mediastinum, as well as accidental microbic infection, with resulting suppuration and sloughing of the sac, are events fraught with danger which occur in the clinical history of these cysts. Bile may enter the cyst and render it sterile by destroying the parasite, thus producing a spontaneous cure in time.

The diagnosis of echinococcus cyst of the liver may be determined by an exploratory puncture. A clear fluid, either neutral or alkaline in reaction, free from albumin and rich in sodium chloride, and containing succinic acid, is obtained. Microscopical examination sometimes

[1] Read before the Medical Society of the State of New York, Oct. 15, 1901.

reveals the knob-like heads, or scolices, and hooklets of the parasite in large quantities.

The treatment of echinococcus cyst of the liver is of an operative character, and consists in excision by partial hepatectomy, whenever feasible, by either the abdominal or transpleural route. R. S. Fowler operated at one sitting, carefully emptying the cyst by aspiration after exposing it, and then after isolation of the liver by large gauze pads, removing the cyst-wall and a thin slice of the adjacent liver substance by means of the thermocautery. Five cases operated upon by this method in my hospital services have all recovered promptly.

In large tumors with many adhesions this radical procedure may not be practicable, in which case the fibrous capsule may be sewn to the edges of the abdominal incision, and the operation completed by opening the sac at once, or the latter may be postponed for three or four days. The cyst-wall may be removed in part or entirely; it frequently sloughs away and may be removed piecemeal at subsequent dressings. In cases in which the cyst is too adherent for removal, final obliteration may be brought about by injections of diluted tincture of iodine (1 to 8). Aspiration of echinococcus cysts and injections of various solutions, or leaving a cannula *in situ* for permanent drainage, are not justifiable procedures.

Simple or Non-Parasitic Cysts of the Liver.—These are of very rare occurrence. Probably a majority of those reported have been sterile hydatid cysts. Those not belonging in this category probably have their origin in dilated lymph-vessels. An exploratory puncture will readily settle the differential diagnosis between echinococcus disease and simple serous cyst, the presence of albumin and the absence of hooklets constituting the characteristic features. The treatment consists of evacuation of the contents of the cyst after drawing the latter through an abdominal incision made over the more prominent portion of the tumor, and suturing the edges of the opening in the cyst to the margins of the abdominal wound, thus establishing permanent drainage. Large cysts that are free from adhesions may be to a large extent extirpated, any remaining portions being attached to the abdominal wall.

Multilocular Cystic Disease.—This is a condition similar to multilocular cystic disease of the kidneys, with which it has been found to be associated. It occurs almost exclusively in elderly persons, or those over sixty. It is of but slight surgical importance, save from the standpoint of differential diagnosis, since the involvement of the entire liver precludes operative interference. It is a very rare pathological condition. In almost all the recorded instances the diagnosis has been made postmortem.

Cystic Adenomata of the Liver.—These arise either from the epithelial cells of the liver or the intrahepatic bile channels. One or more cysts may be present. König and Schmidt have each recorded a successful case in which a cystic adenoma of the liver was removed by operation. To these I have to add a third, from my own experience, the tumor, the size of an English walnut, appearing prominently in the epigastrium. A median incision was made, the tumor exposed and removed, together with a portion of the surrounding liver substance, by means of the thermocautery. The patient, at the end of three years, has not suffered from a return of the growth.

Dermoid Cysts of the Liver.—As an isolated affection, these are unknown. In the case described by Hulke the dermoid tumors of the liver occurred in association with dermoid tumors of both ovaries. It would scarcely seem warranted to assert that the tumors of the liver were secondary to those of the ovaries. The discovery of a dermoid cyst of the liver in the course of a laparotomy, for it is probable that only in this way a diagnosis would be established, should be followed by a dissection of the entire tumor from the hepatic tissue. If this is found to be impracticable the same course may be pursued as recommended in large and adherent echinococcus cysts, namely, evacuation and suturing of the edges of the incision to the margins of the abdominal wound. Cases in which suppurative changes have taken place should be treated as abscesses of the liver.

Angioma of the liver occurs as a localized tumor of variable size situated beneath the capsule of Glisson, and consisting of diseased blood-vessels. The disease is of but slight surgical importance. Growths that are of congenital origin soon destroy the patient, while the acquired cases are innocent in character and do not demand treatment, although Eiselberg removed such a growth from the right lobe of the liver by means of the thermocautery.

Fibromata and *adenomata* of the liver are of interest surgically principally for the reason that growths of this kind are the foundation for primary sarcoma and carcinoma of the liver. The probability of this serves to emphasize the importance of definitely exploring and broadly extirpating any tumor of the liver springing from either the epithelial or connective tissue structure in as early a stage of its development as possible.

Botyroid Liver, so called from its resemblance to a bunch of grapes, is a condition which is the final result of a syphilitic hepatitis. The changes in the liver are permanent and possess no surgical interest.

Accessory Lobes.—Occasionally these may become sufficiently hypertrophied to be mistaken for new growths. Keen attributes such a case to Martin, of Birmingham, in which the growth was supposed to be a renal cyst until an abdominal section revealed its true character. The base of the lobe was ligated and the gall-bladder removed with the mass. Recovery followed.

Syphilitic Gummata may break down and find their way to the surface, thus simulating a neoplasm of the liver. These should not be made

the subjects of operative attacks, unless the administration of potassium iodide has failed to ameliorate whatever symptoms they may produce.

It is customary to consider *floating* or *movable liver* in connection with tumors of the liver. This condition is either congenital or acquired. In the latter event it is due to tight lacing, or to dragging upon the organ by an enlarged gall-bladder, or it may be secondary to large tumors. In lacing liver the constricted portion becomes movable. The congenital variety is usually associated with enteroptosis. The mobility depends upon the lengthening of the suspensory, lateral and coronary ligaments; in rare instances the latter are absent. It occurs much more frequently in women than in men. In extreme degrees of mobility there is more or less continuous distress and exacerbations of severe pain; jaundice may be present at times. Digestive disturbances are common. Examination discloses a movable tumor the size and shape of the liver and resonance in the hepatic region. In lacing liver the constricted lobes may be united by suture, as suggested by Billroth, followed by Hacker, Fecherning, and others. In a case of congenital origin which came under my care over two years ago, the patient then being twenty years of age, an excellent result was obtained and maintained by fixation to the diaphragm and the sheath of the right rectus muscle through the medium of the broad surfaces of the greatly lengthened suspensory ligament. Kangaroo tendon sutures were employed.

MEDICAL PROGRESS.

PATHOLOGY, BACTERIOLOGY AND HISTOLOGY.

Formation of Poisons in the Organism.—Of the many substances which have a deleterious influence on the red blood-cells, only a few are known as organic or inorganic poisons. In the numerous diseases in which one can observe only the destructive effect on the blood-corpuscles, but little is known of the nature of the toxins themselves. E. GRAWITZ (Deut. med. Woch,. Dec. 26, 1901) differentiates two processes which may bring about a hemocytolysis. The first is dominated a "plasmotropic" effect and may be considered as due to toxins which, while leaving the corpuscles in the circulation intact, destroy the same in the liver, the spleen, and the marrow, without there being an extrusion of hemoglobin into the plasma. The other he calls "plasmolysis" and includes those poisons which cause a disintegration of the red cells in the circulation with the appearance of a hemoglobinemia and its sequelæ. The type of the former class is lead, which causes a granular degeneration of the red cells in the organs, but no plasmolysis in the circulating blood. A similar phenomenon was observed in patients subject to hemorrhages from gastric ulcer or carcinoma or who had swallowed a large amount of blood from a pulmonary hemorrhage, the condition disappearing when the bleeding had ceased. In patients with external hemorrhages this was not found. The administration of various hemoglobin preparations also caused a granular degeneration of the red cells, increased by continued and larger doses, and disappearing when the drug was stopped. The author believes from his clinical experience that the passage of blood or preparations of blood through the intestinal tract causes the formation of substances which exert a true plasmotropic influence on the red cells. These observations may also serve to explain the anemia found in anchylostoma infection, in which not only the actual loss of blood from continuous hemorrhages must be considered, but also the auto-intoxication from the absorption of poisons developed in the extruded blood.

Amebic Abscess of Liver.—Of clinical interest in this case reported by J. A. SCOTT (Proc. of the Patholog. Society of Philadelphia, Nov., 1901) are a large latent abscess with no history of previous dysentery, sudden rupture into right pleural sac, with all the signs of acute hemorrhagic pleurisy, and the development and subsequent disappearance of a pyopneumothorax. The pleural exudate was a thin brownish-red material, with a heavier brownish flocculent sediment, containing fatty leucocytes, but no amebæ, and sterile on culture. At autopsy amebæ were found by Dr. Flexner in the wall of the abscess; there was great thickening of the pleura above the abscess, and in the colon were found pigmented scars of some former ulceration (dysentery).

Hematic Antidotes.—Probably no author has been more active in developing the theory of hematic antidotes than Ehrlich. PROFESSOR GRUBER (Med. Press and Circ., Dec. 25, 1901) reviews the whole matter in the following terms: Ehrlich believes the action of antitoxins on toxins depends purely on the nature of a chemical transposition of elements which can be demonstrated according to the law of multiples. Concentration and temperature largely influence the results, although the toxins under any condition have the notable power of diffusion in gelatinous media. An excellent parallel of this action is to be found in the union between saponins and cholesterin of the blood-serum. This combination destroys the hemolytic action of the saponins. It must be borne in mind, however, that the combination of toxins and antitoxins does not abolish their individual existence. If the mixture be heated to 68° C. the poisons will be found as active as ever, although a considerable time may have elapsed. Therefore one must conclude that the union is not chemical. Furthermore, this explains why in some cases after combination poisonous effects are seen after injecting animals with the fluid. Another property of the toxins is that their power decreases on standing. If the animal does not die an apparent latent period appears before the paralysis and edema set in. This modified toxin he has named toxone and a still further modification he has called toxoid. He assures us that the bacillus of diphtheria produces toxins and toxones and that the latter may be converted into toxoids. Another property of these organic poisons is their great power. One-fourth of a milligram of bacterial poison will kill a man, while it will take seventy of strychnine. Notwithstanding this deadly effect, the dose, or even a larger dose, will go through a period of incubation lasting in some cases many weeks. It seems also a fact that the more sensitive an animal is to the poison, the more quickly the injection is worked out of the blood-current into the general system. Again, if the animal is injected with tetanic and antitetanic toxin at the same time, it will be found that the same quantity of the latter is required to neutralize the former as in the laboratory experiments *in vitro*. If, however, seven or eight minutes elapse before injecting the antitoxin, its quantity must be largely increased until fifteen minutes have passed, when the serum dose seems to have be-

come stationary and usually inert against the toxins. In susceptible animals the poison passes so rapidly out of the blood into the system that death occurs before antitoxin can have any effect. In some cases tetanic toxin taken from the brain of susceptible animals is inert, although that recovered from other organs is still active. Ehrlich explains this by stating that it combines with various salts in the nervous system, which render it temporarily inactive. The incubation period for these toxins varies with the mode of injection. Subcutaneous and intravenous injections have much longer incubation periods than intracerebral applications.

Elastic Tissue in Cicatrices.—The question of proliferation of elastic tissue has been much discussed. Guttentag of Unna denied the presence of elastic fibers in cicatricial tissue; Passarge, Kromejer and others assert that they appear after a time in the newly-formed tissue; some observers believe them to be derived from the elastic fibers in normal tissue, others that they have their origin in the connective tissue cells. P. Pezzolini (Gazz. degli Osped., Dec. 22, 1901) through a series of experiments has proved their derivation to be from adult elastic fibers. Wounds of uniform size were produced in dogs, some of which were allowed to heal in the regular course of cicatrization; in others skin grafts were introduced. After the wounds were healed, specimens including the cicatricial and surrounding tissue were excised, and, after preparation and staining, examined under the microscope with the following findings: The first appearance of new elastic fibers was from the sixtieth to seventieth day, the number varying according to the age of the cicatrix; they were first seen at the lateral margins of the cicatrix, while their development in the center was much delayed, except in those wounds in which adult elastic tissue had been introduced by grafting, in which case, simultaneously with the formation of fibers from the elastic tissue of the surrounding skin, new fibers were formed from the transplanted elastic tissue of the graft. The author was able to observe the division of the ends of the cut elastic fibers, and their development and extension into the connective tissue of the cicatrix.

SURGERY.

Treatment of Inoperable Tumors.—Of the several injection methods for the treatment of inoperable malignant growths, the results obtained from the use of methylene blue and Coley's mixture in a series of cases are reported by C. George (Phil. Med. Jour., Jan. 11, 1902). Methylene blue was used in two cases of sarcoma of the neck. The injections were given daily in gradually-increasing doses of from five to thirty minims of a 1 to 500 aqueous solution directly into the tumor. A marked diminution in the size of the tumor was noted, with some relief from pressure symptoms, but there was an excessive stimulation of tumor cells in the neighborhood. Both cases terminated fatally. Coley's mixture of the toxins of streptococcus erysipelatis and bacillus prodigiosus was used in four cases, sarcomas of the upper jaw, forearm, mandible, and lymphosarcoma of the neck. In all cases there was increased growth due to the irritant action of the toxins and the absorption of the latter, together with the products of the necrotic changes, caused general weakness and depression. One case which seemed improved was an ordinary granulation tissue tumor, with no evidence of sarcomatous tissue in it. As the diagnosis between round-cell sarcoma and ordinary granulation tissue is difficult, there is a question as to whether certain cases reported improved were in reality true sarcomata.

Acute Pancreatis with Fat Necrosis.—An interesting case is reported by W. J. Mayo (Jour. Amer. Med. Assoc., Jan. 11, 1902). The patient had suffered from attacks of indigestion for two years previously when he was seized with sudden epigastric pain, accompanied by marked symptoms of collapse. Acute intestinal obstruction developed, with other signs upon which a diagnosis of gangrenous cholecystitis with perforation was based. Operation was done. The signs of fat necrosis were evident. The pancreas was found enlarged, the gall-bladder thickened and containing a stone as large as an egg. The stone was removed, a rubber tube inserted into the gall-bladder and brought out in the right groin. A free discharge lasted for several days, containing both pancreatic fluid and bile. The patient was in a critical condition for a week, but made a complete recovery in seven. The gall-stone was evidently the cause of cholangitis, which extended to the pancreatic ducts, with resultant pancreatitis and fat necrosis, the operation checking the process short of abscess formation.

Colon Transplantation.—Not only the magnitude of the operation itself, but the very unfortunate condition of a patient subsequently afflicted with an artificial anus, have hitherto largely discouraged attempts at extensive resection of the colon. De Quervain (Rev. Méd. de la Suisse Rom., Dec. 20, 1901) has suggested a new operation which seems at least to obviate the necessity of the preternatural anus. He was led by the researches of Kummel on the vascularization of the colon to believe that considerable division of the mesocolon was still compatible with the life of the gut. In a case in which he was compelled to resect the descending colon, therefore, he freed the mesocolon and sewed it to the rectum with very perfect results. He believes that the rectum might be extirpated and the gut carried down and implanted at the anus. The operation is indicated only in cases of extensive malignant or mycotic disease of the descending colon, or of incurable polypoid colitis, or of combined disease of rectum and colon.

Fracture of the Lower Jaw.—The variety of splint recommended for fracture of the lower jaw is proof of the difficulty of treating this common injury. J. Weiting (C'blatt f. Chir., 1901, No. 51) had a difficult case of this kind and treated it in the following manner: A kick from a horse had caused a threefold break in the bone, one on each side at about the same point, plainly visible and palpable from the mouth, with all the typical symptoms. The third break was complicated and between the incisor and the eye teeth. There was moderate overriding of the fragments. After numerous failures to maintain reduction with various kinds of rubber splint, he carried out the following procedure: A hole was drilled through the alveolar margin, a little to the left of the median line, near the point where the mucous membrane is folded over between the bone and the lip. Through this hole a long silver wire was passed and wound on the left side about the canine tooth. In this way the drilling of a second hole was avoided and, moreover, the oblique direction of the silver wire aided in correcting the overriding and displacement of the fragments at this point. Thus, therefore, one of the fractures was reduced and fixed. It was found that by pulling upward lightly on the wire perfect reduction and fixation of the other two breaks was brought about. This suggested the plan of taking a strip of zinc, bending it into a hoop and passing it around the neck on a level with the body of the lower jaw. Here it was retained by a plaster-of-Paris helmet bandage which extended from the brow to the root of the neck. The hoop of zinc passed out of the bandage opposite the chin, where the silver wire previously described was fastened in notches. In this way with the least possible inconvenience to the patient a cure was obtained. So inge-

nious and rational a device to overcome a difficult surgical problem is worthy of note and trial.

Oophorectomy for Mammary Carcinoma; Another Version.—According to views recently expressed at St. Bartholomew's Hospital, this new mode of treatment has not all the advantages which have been claimed for it. H. T. Butlin (Brit. Med. Jour., Jan. 4, 1902), in beginning his argument against it, says: "Before I speak of the cases in which the operation and thyroid extract have been employed, I must draw your attention to his (Dr. Beatson, of Glasgow) theory. He considered cancer of the breast to be a local proliferation of epithelium, and he said that when the cells had proliferated and increased in number they gradually swarmed out into the surrounding tissues and produced the microscopical structure of cancer. He said there was no parasitic character to the disorder. He began to wonder how, within the bounds of this premise, the disease might be limited. In ordinary lactation there is a similar proliferation of epithelium, but with this difference—the tissue, instead of heaping up in the ascini, as in carcinoma, undergoes fatty degeneration and passes away as milk. During this physiologic process the woman never menstruates. With very unusual ingenuity he argued that similar conditions might be produced by removing the ovaries and the piling up of the cells in the ascini stopped." This is, in effect, Dr. Beatson's theory. Dr. Butlin then reviews the rather unpromising history of the cases treated by the new method and closes by saying that the evidence so far all pointed toward the desirability of local treatment and that in all probability Dr. Beatson's method would never supplant this operation, no matter what might be the effects of employing them together. This observation he bases on the following conclusions: (1) The hope that can be given to a goodly number of women nowadays that operation may be quite successful. (2) If the disease still kill the patient, it may do so by recurring in some distant organ and with much less pain and suffering. (3) If it recur *in situ* in the form of nodules, the patients generally suffer far less than if no operation had been performed.

Burns from Roentgen Rays.—Since the Roentgen rays have been so generally employed for diagnostic and therapeutic purposes, the peculiar but characteristic effects of prolonged use of these rays upon certain people have become an important subject for investigation and treatment. C. Beck (Med. Rec., Jan. 18, 1902) says that the most characteristic difference between ordinary burns and integumental changes produced by the Roentgen rays is the fact that the latter do not manifest themselves before the lapse of a period of incubation, as a rule, after about two weeks. This latent period in burns of the first degree is followed by a hyperemic stage, at first light, later dark, and, finally, becoming brown and scaly. After a few weeks there is complete recovery sometimes followed by pigmentation. In the bullous form intense reaction occurs and depilation if the area was covered by hair. Pigmentation and teleangiectasis nearly always remain. In the necrotic type reaction appears within a few days and requires months for its cure. The constant contact with these rays, which many are obliged to subject themselves to in running machines, has resulted in the so-called terracotta hands. The skin is wrinkled, shriveled, vulnerable and partially cracked, the nails horny and the phalanges so much thickened that there is tension when motion is exercised. The specific action which seems to be due to these rays has been taken advantage of in the treatment of various skin diseases and also in malignant tumors. The value of them is still somewhat uncertain, but their marked bactericidal properties cannot be doubted any longer. Many valuable hints for rational therapy of bacterial diseases will certainly be forthcoming. In regard to precautions it may be said that the healthy skin surfaces should be protected by tin-foil or lead plates during the process of irradiation for therapeutic purposes. The treatment of the burns is the same as for ordinary burns of a similar character.

Omental Anastomosis for Cirrhosis of the Liver.—Numerous cases have been reported of recoveries from the symptoms of cirrhosis by surgical treatment and the operation is now rather frequently performed. T. C. Witherspoon (St. Louis Med. Rev., Jan. 11, 1902) reviews the literature on the subject and advises a more certain and general formation of adhesions between the surface of the liver and diaphragm. The incision may be made, under cocaine, above the umbilicus; before the omentum is sewn to the anterior abdominal wall the peritoneum around the wound should be scrubbed thoroughly with a piece of gauze, and it is of decided value also to rub off the liver peritoneal cells just under the diaphragm to allow of adhesion of this organ to the wall. Undoubtedly this improves the circulation of the liver superficially and may put off the day when the necessary liver incompetency appears and auto-intoxication arises. The parietal peritoneum may be separated around the wound and the omentum tucked beneath it to secure more perfect union, or the peritoneum may be excised for a variable distance and the omentum attached to the denuded surface.

Treatment of Appendicitis.—The mortality from appendicitis is certainly much higher than it should be and when young men and women in the prime of life and with excellent health are carried to their graves after an illness of only four or five days the medical profession must realize that their duties have been very poorly performed and upon their shoulders rests the responsibility for these untimely deaths. J. H. Carstens (N. Y. Med. Jour., Jan. 18, 1902) refers to the prevalent idea that, if the patient is put upon a starvation diet and the inflammatory process allowed to subside, he will be better able to stand an operation. It is true that in many mild attacks this treatment will be satisfactory, but in the present stage of diagnostic skill it is impossible for one to determine the exact condition within and even with mild symptoms a gangrenous process or an abscess just ready to rupture may be present. Furthermore, after a starvation diet of two or three weeks, especially if an infective process has been present, the patient's condition is certainly not improved nor are the local processes more favorable for removal. With our present knowledge the only conservative treatment which is safe is immediate operation as soon as the diagnosis is made, for it is most radical for any physician or surgeon to dare to leave such a treacherous condition within the abdominal cavity of his patient.

Primary Abdominal Tuberculosis.—Although tuberculosis undoubtedly originates in a large percentage of cases in the respiratory tract, it can be no longer denied that primary tuberculosis of the belly is a frequent condition. L. F. Flick (Penn. Med. Jour., Dec., 1901) believes that the bacilli are often taken in with the food and are absorbed by the intestinal lymphatics and lodge in the mesenteric glands. They probably do not multiply in the intestinal canal, for the conditions there are not favorable to their growth. Since the suggestion and partial proof have been offered that bovine tuberculosis is not communicable to the human being, this theory of intestinal infection becomes less plausible and yet there are so many ways that the dried infected human sputum may contaminate food and drink that such an infection does not seem at all strange. The

treatment of such cases is, of course, surgical and the important part of it is to expose the abdominal cavity as much as possible and manipulate the contents with the greatest freedom. Dr. J. Price recommends the free use of iodoform in these cases and says that he has used even an ounce in one case without any disagreeable after-effects.

The X-ray in the Treatment of Sarcoma.—This method is advocated in inoperable cases and also as a prophylactic against recurrence in patients who have been treated surgically, by W. A. Pussey (Jour. Amer. Med. Assoc., Jan. 18, 1902). He reports a case in which a clinical and pathological diagnosis was made of a small round-cell sarcoma of the neck. Operation was done, but shortly afterward a similar tumor appeared on the other side of the neck. X-ray exposures were tried for twenty-one days, with a hard tube and a weak light, about 5 cm. from the surface and for from ten to fifteen minutes at a time. Toward the last a pronounced dermatitis developed; the exposures were then stopped. Within ten days of beginning treatment, the tumor had shrunken and motion was freer, and when the exposures were discontinued only a small (almond-sized) gland remained, freely movable and painless. Up to date (Jan. 12, 1902) no change had taken place. In a second case, one of osteosarcoma of the shoulder, far advanced and accompanied by profound cachexia, no improvement was noticed except relief from pain. In a third case of inoperable sarcoma of the pectoral muscles and the shoulder, a like result was observed. Both patients were evidently beyond the reach of any form of treatment. In two cases of Hodgkin's disease which were subjected to a series of X-ray exposures it was found that the further growth of the enlarged glands was inhibited and they themselves became reduced in size.

Intraperitoneal Rupture of the Kidney.—This serious surgical condition is not very uncommon and always deserves prompt, radical treatment. F. de Quervain (Deutsch. Z'schrift f. Chir., Dec., 1901) has been experimenting on animals with reference to the diagnosis and the treatment of damage to the kidneys. The following are his conclusions: The differential diagnosis between intra- and extraperitoneal rupture of the kidney, on the one hand, and, on the other hand, damage to other organs of the body, individually or as complications of the former, presents very great difficulties; consequently, it is often necessary to be satisfied with a probable diagnosis. Further progress must be made, especially in determining a damage to the peritoneum by urine and blood, leading to an infectious peritonitis. Such may also come from rupture of the bowels. We are not aided much in this particular by the usual diagnostic aid of the blood-examination. It is also necessary for the sake of prognosis to distinguish between very great damage to the organ and lesser degrees of contusion. In both damage to the diaphragm and the danger of bleeding are important, because within the abdomen bleeding finds no real obstacle. As a rule, however, there is only danger of grave injuries or of peritonitis through infection. The severe cases usually die early from the loss of blood and from shock. Consequently, peritonitis is not often the cause of death. In the less severe cases the picture is somewhat different because not only is the danger from bleeding much less, but the whole process is slower and permits the formation of adhesions which localize the abscess. In the treatment of this condition it seems far wiser not to interfere in the mild cases, but they should be carefully watched. If unfavorable symptoms develop, indications for treatment may be followed. The severe cases, on the other hand, should be operated on as quickly as possible, so that the sources of hemorrhage may be reached and checked and all possible damage to the other organs of the abdomen repaired.

Intestinal Anastomosis.—Suture of the intestines, especially after the removal of part of them, has been an interesting problem for many years. J. Frank (Ann. of Surg., Jan., 1902) compares the mechanical method with the so-called suture methods of uniting the bowel and lays down the following essentials for making the operation successful: Simplicity of application, saving of time, uniformity of coaptation, arrest of hemorrhage, slight contraction of scar, proper relation of coats of the intestine at the point of union, avoidance of infection, least disturbance of peristalsis, avoidance of pocketing and shelving, reduction of mortality, and minimum number of lesions. The majority of these are self-explanatory and, therefore, need no further comment, except that, after recognizing them, the following conclusions may be drawn in favor of the mechanical means of anastomosis: (1) With no other method can be obtained all the excellent qualities in such an ingenious combination as with the Murphy button. (2) No suture method can show such a low mortality. (3) The perfect holding together of the intestinal ends throughout their circumference with the Murphy button obviates the danger of leak. Von Chlumski subjected all the methods to pressure with water and demonstrated the inferiority of the suture methods. For end-to-end anastomosis the button is the only device which has achieved great triumph. In this operation the suture methods show their greatest mortality.

Stitch Abscesses.—These annoying abscesses depend usually upon two conditions, namely, the state of the surgeon's hands and the preparation of the patient's skin. A. E. Maylard (Ann. of Surg., Jan., 1902) says that he has found the best means of sterilizing the hands to consist in plunging them for five or ten minutes into water as hot as can be borne. The effect of this is to dilate the capillary vessels as is indicated by the redness of the skin and thus to excite active secretion of the two sets of glands. By the prolonged exposure to the hot water and by the copious secretion the surface epithelium is rendered sodden and then removed by rubbing the hands together under the water and then by using ordinary soap. Lastly, the hands are washed off in a warm solution of carbolic acid (1 to 40). This is the lotion kept in use throughout the operation for the surgeon's hands. For cleansing the skin of the patient he has found the following method very effectual: First, the skin is scrubbed in the usual way with soap and water and with turpentine, alcohol or ether if necessary. Then over a wide area hydrated lanolin oleate of mercury (20 per cent.) is rubbed in. The same ointment is smeared on a piece of gauze and placed on the skin for twelve to twenty-four hours. Then another quantity of the ointment is rubbed in and a second piece of gauze smeared with it and applied. This is not removed until the time of the operation. At least twenty-four hours, preferably forty-eight hours, should be devoted to the preparation of the patient in this way. Ten minutes are required for each "rubbing in" of the ointment. On the operating-table the piece of gauze is removed and any superfluous ointment is rubbed off with a piece of dry sterilized gauze. The skin of the patient is now ready for operation. The originator of this method states that chemical examination of the skin for mercury was negative—probably because the quantity was so very minute in the first place, and, in the second place, too rapidly absorbed to admit of detection. Bacteriologically, the number of germs common in the skin was found to be very much reduced. Those which were present were due, no doubt, to the fact that it is impossible by any means to reach

all the possible places where they abound, namely, hair follicles, sebaceous and sweat-glands, and the various layers of the epithelium. However, the decrease in their number was so great as to support the value of the method. The clinical records gave incontestable proof of its value. On these grounds he commends it for trial. It is, of course, available only in cases where a long preliminary preparation of the patient is possible. For emergency operations it could hardly be used.

Gastro-enterostomy.—The regurgitation of bile into the stomach after a gastro-enterostomy has proved in some cases an insurmountable obstacle, although the most approved methods of operating have been followed. E. TAVEL (Revue de Chir., Dec. 10, 1901) relates a case in which several operations were necessary to overcome it. The patient suffered from hyperchlorhydria of obstinate type. The first operation was done November 22, 1896, by Dr. G. Sick (Hamburg). It was the typical Kocher method of gastro-enterostomy, anterior and antecolic. The union between the stomach and the intestines was on the greater curvature of the stomach near the pylorus. On January 16, 1897, Mikulicz (Breslau) did the second operation in order to relieve the dilatation of the stomach due to the fact that the anastomosis has contracted to the size of a lead pencil. At this operation a gastro-enterostomoplasis and entero-anastomosis were done after the method of Braun-Jaboulay. This operation was unsatisfactory, because the symptoms continued equally severe and obstinate. The third operation was done by Kocher (Berne) in June, 1897. It consisted chiefly in a folding of the afferent loop of the intestine, after the method of Von Hacker, to which was added an elongation of the mesentery of this same afferent loop. This was followed by considerable improvement in the symptoms, but still there was much to be desired. The fourth operation was, therefore, undertaken in August, 1897, by Tavel at Berne. During it the duodenum was separated from the stomach just beyond the pylorus and an attempt was made to restore the abdominal wall. This served to prevent all flow of bile by reversed action of the bowel into the stomach, but still another step was necessary. At the fifth operation September 4, 1897, by the same surgeon, the afferent loop of the intestine was cut away. The condition in the abdomen was then as follows: As the stomach had been closed just beyond the pylorus, its outlet consisted in an anastomosis with the small intestine as just described. The bowel was so arranged as to make its peristalsis pass in the same direction as that of the stomach. Behind this loop of the intestine lay the colon running transversely from side to side. From beneath this structure appeared the stump of the afferent loop created at the fifth operation. Just beneath the colon it joined the loop from the stomach by a lateral anastomosis. In this way it will be seen that the bile could not reach the stomach except by traveling against the peristalsis and against food from the stomach vertically upward for the distance represented by the separation between the stomach and the colon. Tavel claims that the results were most satisfactory.

Gastrostomy.—The necessity for making an opening into the stomach by means of which food may be given when the normal passages are out of function is often urgent to the last degree. A. DEPAGE (Jour. de Chir. et Annales de la Soc. Belge de Chir., Nov. and Dec., 1901) presents the following exceedingly ingenious plan: In the front wall of the stomach, extending almost from curvature to curvature and opposite the junction of the left and middle thirds of the organ, he makes a long horseshoe-shaped flap, with the base upward and the sides parallel and wide enough to permit the flap to be folded and sewn around a rubber tube. Placing this tube in position he folds the flap of the organ about it so that mucous membrane is everywhere in contact with it. This brings the peritoneal surfaces in contact. In a similar way the hole representing the wall of the stomach removed in the flap is closed in the same way. This makes a long, continuous suture line which begins below at the apex of the flap and ends above at the tip of the new inlet to the stomach. This new gullet, as it might be called, is then passed through the abdominal wall and secured there. After union has taken place food may be easily passed into it. It is a most successful and certain method of providing a well-protected and permanent false opening into the stomach.

ANATOMY AND PHYSIOLOGY.

Conversion of Pancreatic Zymogens into Enzymes.—Knowledge concerning the zymogen of the proteolytic ferment of the pancreas has received scarcely any additions since 1875. Although it is known that the rennet ferment of the stomach does not exist as such in the gastric juice, but as a zymogen, no proof seems to have been adduced of the existence of a similar body in the pancreas. H. M. VERNON (Jour. Phys., Dec. 23, 1901) has made a series of observations upon these closely-related ferments in order to determine more exactly the conditions under which the zymogens of trypsin set free their enzymes, the rapidity of such transformation, and the degree of stability possessed by these enzymes when once they are formed. He finds that extracts of a fresh pancreatic gland as a rule show no ferment activity for some days and then more or less suddenly develop nearly their maximum power. When the glands from several different animals are minced together and extracted the ferment activity begins to develop at once. The destructibility of the trypsin, as tested by keeping the diluted extract for one hour at 38° C. with 4-per-cent. NaCl and determining the percentage of ferment destroyed at the end of this time, varies concomitantly with the activity of the extract. If filtered glycerin extracts of zymogen be diluted with water they spontaneously develop tryptic power at a rate increasing with the degree of dilution. The rennet ferment in inactive extracts is set free as well as the tryptic, but it was found that the liberation of the ferment from its zymogen was effected not by the rennet ferment, but by the tryptic. It was found that the amount of ferment liberated by exposure of the minced gland substance to the air for twenty or more hours was as a rule very small, most of the ferment being set free after the addition of the extracting liquid. The addition of small quantities of tryptic digestion products to the inactive extracts was found to have a moderate enzyme liberating effect. When oxygen or CO_2 was bubbled for one to three hours through diluted glycerin extract kept at 38° C., the enzyme was not liberated any more rapidly or slowly than in the unaerated extract. If, however, 1 per cent. of an active extract was added, then in one hour the oxygen increased the enzyme formation from 28 to 43 per cent., while the CO_2 decreased it from 6.4 to 12 per cent.

Movements of the Intestines as Studied by Means of the Roentgen Rays.—The investigations of the intestinal movements have been beset by the same difficulties that characterize the investigation of the gastric mechanism. Pathological subjects or animals subjected to the disturbing action of drugs or serious operations have been the only sources of our knowledge. Under these conditions a considerable difference of opinion as to the nature of the normal movements of the intestine has existed. In order to arrive at a clearer understanding of this subject W. B. CANNON (Amer. Jour. Phys.,

Jan., 1901) has utilized the Roentgen ray. The observations were made upon cats. Subnitrate of bismuth one-tenth to one-third the weight of the food was mixed with what the animals ate. He finds that in this manner the movements of the intestinal contents and thereby the movements of the intestinal walls are visible on the fluorescent screen. The activity most commonly seen in the small intestine is the simultaneous division of the food in a coil into small segments and a rhythmic repetition of the segmentation each time applied to the new segments formed from parts of those just divided. Peristalsis is usually combined with segmentation. The ileocecal valve is thoroughly competent for food entering the colon from the ileum. The usual movement of the transverse and ascending colon and the cecum is an antiperistalsis. This recurs in periods about every fifteen minutes and each period lasts about five minutes. This gives a new significance to the ileocecal valve, for the food now in a closed sac is churned and mixed by the constrictions running toward the cecum and again exposed to the absorbing walls without any interference with the process in the small intestine. As soon as new food enters the large intestine a strong general contraction takes place along the cecum and ascending colon; a moment later antiperistaltic waves begin to pass. With accumulation of food in the transverse colon deep tonic constrictions appear one after another and carry the food into the descending colon. The observations have revealed no evidence of antiperistalsis in the small intestine, but since the ileocecal valve will allow nutrient material under pressure to pass backward the antiperistalsis of the large intestine may force into the small intestine considerable portions of large nutrient enema. Signs of emotion such as fear, distress or rage are accompanied by a total cessation of the movements of both small and large intestine. The movements continue in the cat both during sleep and at night.

Formation of Bile Pigment and Bile Acids.—That these substances are not formed by the liver-cells is demonstrated in a series of experiments by A. C. Croftan (Phil. Med. Jour., Jan. 18, 1902), which also show that such pigments and acids can be formed in various parts of the organism other than the liver, and that they can be formed from hemoglobin outside of the organism by a purely chemical, fermentative process and without the intervention of the liver-cells. To determine the rôle of the latter in the formation of bile pigments and acids, a watery extract of fresh liver-cells (of a calf) was prepared, from which these had been extracted by alcohol. To this was added a solution of hemoglobin and dextrose (1 per cent. in the proportion of one to four. It was found at the end of a week that all the hemoglobin was destroyed; the fluid contained the bile acids and the sediment substances which gave the typical reaction of bile pigments, showing that a conversion of hemoglobin into bile pigment and acids had taken place without any "vital" action on the part of the liver-cells; the process was chemical, and the active agent a substance that was soluble in water and therefore unorganized. As the process resembled a true digestion, the fluid was tested for the presence of a ferment. Fibrin flakes placed in the liver-cell extract, and the mixture alkalinized with a 7-per-cent. soda solution, were partially digested, and albumose, peptone and tyrosin were found. The probability of the active substance being *trypsin* was substantiated by confirmatory tests, solutions of both giving the same reactions. Moreover, when a solution of trypsin was added to a mixture of hemoglobin and dextrose, after a week's time the fluid contained bile acids and the sediment, pigment. It is probable that the trypsin is in part normally absorbed from the intestine, but that the greater part reaches the liver via the pancreatic veins in the portal blood or via the lymphatics in the hepatic artery. If the formation of bile acids and pigments from hemoglobin by the action of trypsin in the presence of dextrose is a purely chemical process and altogether independent of the specific action of any particular group of cells, one must conclude that wherever in the body free hemoglobin is present, together with dextrose and trypsin, this conversion into bile products can occur and not necessarily in the liver alone.

MEDICINE.

Rapidly-fatal Scarlatina.—The most rapidly-fatal case mentioned in Nothnagel's System of Medicine died in twenty-six hours; in Keating's Cyclopedia, in twenty-four hours. Bessey and Goodhart had seen cases die in twenty-four hours. W. S. Morrow (Montreal Med. Jour., Dec., 1901) cites the case of a boy of two years and eleven months who came in from play and felt sick and vomited at five in the afternoon, had a loose, dark-colored stool in the night, played with his brother in bed the next morning, ate a baked apple at noon, and died in convulsions at half past five. No physician was in attendance, but four hours after death reddish patches were visible on abdomen and thighs, the glands at the angle of the jaw were enlarged, and, on prying open the mouth, the tonsils were seen large and red, the redness extending upward on to the palate. The viscera were negative. A scarlatina epidemic was raging at the time, and a brother developed the disease a few days later.

Interventricular Aneurism.—The patient had had syphilis and five years ago had a severe fall from a horse. Three years ago he noticed palpitation and dyspnea, with precordial pain and fainting spells. The precordium was prominent and bulging and there was an apparent area of pulsation, 5 cm. in diameter, in the third left interspace. Over this area was heard a systolic murmur most intense over and above the second costal cartilage. There was a marked thrill. At intervals the patient had attacks of faintness with rapid feeble pulse and failure of eyesight. The autopsy, performed by R. G. Curtin (Proc. of the Path. Soc. of Phila., Nov., 1901) showed a saccular dilatation about the size of a walnut above the origin of the aorta anteriorly; the left auricle and mitral valve were much dilated, and the undefended portion of the interventricular septum was found bulging into the right ventricle, into which it opened through a small orifice, probably the result of ulceration. The aneurism was large enough to hold a good-sized walnut.

Amebic Dysentery.—This is a disease which has so rarely been described in children that the diagnosis is probably never entertained by the practitioner. Yet within a short space of time five cases were identified and successfully treated by S. Amberg (Bull. J. H. Hosp., Dec., 1901) at the Johns Hopkins Hospital. The patients ranged in age from two to five years, and illustrated a moderately severe type of the disease, with the exception of one child who was very seriously sick. The clinical picture in these cases was very indefinite. The appetite and general health were good, fever and acceleration of the pulse were hardly noticeable, and the blood-examination showed only a very moderate anemia of the secondary type. Stools varied from two to six in twenty-four hours, were rarely associated with pain, and presented nothing characteristic to the eye. They were of every degree of consistence and might, or might not, show admixture of blood. The odor was always most offensive. Microscopically, three very typical structures are to be found, namely, live amebæ con-

taining red blood-cells, Charcot-Leyden crystals, and numerous eosinophile cells. The presence of either of the latter elements should make the observer extremely suspicious of amebic dysentery, as they occur in no other condition except helminthiasis, which can easily be excluded. The presence of the ameba is, of course, final. Treatment consists in irrigations twice daily with solutions of quinine, 1 to 5,000; the rest of the treatment is merely adjuvant.

Bruit de Galop.—French doctors distinguish between a "bruit de rappel," in which there is a reduplication of the second sound of the heart, and a "bruit de galop," in which there is a reduplication of the first sound. It is upon the subject of the latter that D'ESPINE (Rev. Méd. de la Suisse Rom., Dec. 20, 1901), who with Potain is the authority on the phenomenon, contributes an interesting résumé. By means of the cardiogram he has established definitely that the first sound of the series is protosystolic in time and not presystolic, as was believed by Potain. He attributes great diagnostic value to the sign, which is always an indication of relative myasthenia on the part of the heart. It occurs most frequently in connection with nephritis, either at the beginning, before compensatory hypertrophy has taken place, or at the end, when insufficiency is already imminent. Very often it is associated with an increase in arteral tension. The mechanism of the sign is simply a double effort on the part of the overstrained ventricle to rid itself of its contents. Coming, as it does, before the actual results of incompensation have made themselves evident, it is of enormous prognostic and therapeutic importance.

Blood of Syphilitics.—Important changes in the blood are said to be found in syphilitics, provided accurate and careful examinations are made. Justus's test has long been of assistance before the secondary rash and depends upon the diminution of the hemoglobin about ten to fifteen per cent. during twenty-four hours succeeding an inunction with mercury. L. H. WARNER (St. Louis Cour. of Med., Dec., 1901) has found that in the first stage the hemoglobin is diminished, but the red cells are about normal in number, as in chlorosis. The leucocytes are increased, but a differential count shows a large increase is lymphocytes. In the secondary stage the hemoglobin is further diminished and the leucocytosis persists. In the third stage there are myelocytes, a marked anemia and frequently eosinophilia. If mercury or iodide of potassium are given in the early stages the young leucocytes (lymphocytes) are decreased and the older forms increased.

Leucocytes in Hepatic Abscess.—In view of the divergent opinions concerning the diagnostic value of the leucocyte-count in abscess of the liver, MOSSE and SARDA (Gaz. hebd. de Méd. et de Chir., Dec. 26, 1901) report their findings in four cases. In three of these cases the leucocyte-count ranged between 19,000 and 26,000. These figures are of no diagnostic value, inasmuch as a hyperleucocytosis of similar grade is found in a variety of hepatic disorders other than abscess. In the fourth case the leucocytes numbered 40,000, but here there was present an ulcerous phlebitis of the inferior vena cava. Differential counts showed an excess of polymorphonuclear leucocytes.

Diagnosis of Syphilis.—It is a mistake to place too much reliance upon the failure to get a history or sign of the initial lesion of syphilis, because the initial lesion may have been too trivial to attract the patient's notice. In women especially, writes J. C. WHITE (Boston Med. and Surg. Jour., Jan. 16, 1902), the primary lesion is often masked. The use of the term "copper color" in describing the syphilitic efflorescence is deplored. In leprosy, tuberculosis and all chronic tissue changes of the skin, if the lesions have existed for a long time and especially on certain sites, they may have a copper-colored or dull reddish hue. So in syphilis also; but as cases occur the copper hue is exceptional, because the practitioner sees more of the earlier manifestations of syphilis than of the later ones. It is of little diagnostic value whether there are lesions on the scalp or not. Alopecia is not a constant or a reliable symptom. It is said that syphilitic children are emaciated, have wrinkled skin, look like little old people, etc. This is true in some cases, but a large proportion of children with syphilis are born plump and healthy and may remain so for some time. The initial lesion may be confounded with *ulcus molle* or with a herpetic eruption. Internal remedies should be withheld while the dagnosis remains in doubt. Herpes is self-limited; it should be protected and let alone, and the diagnosis solves itself. The soft ulcer, if it does not spread and if it is simply kept clean, gets well under local treatment; it does not undergo marked infiltration and demands no internal treatment. If it spreads rapidly, herpes and the primary lesion of syphilis are excluded. A definite diagnosis should be made before cauterizing. Except in rare malignant forms of syphilis, it is almost a criminal offence to give iodide of potassium in the early stages or while the diagnosis is in doubt, because it is wholly unnecessary and leads to serious errors with regard to the disease afterward. Most dermatologists probably cannot distinguish between possible syphilitic manifestations and an iodide eruption. Scabies must be thought of when discrete lesions are noticed on the penis. A rapidly developing syphilitic rash with fever may simulate measles. Varicella and variola may be mistaken for syphilis when diagnosis must be made at sight. Syphilis may show itself on the scalp in the form of seborrheal scales. The most characteristic form of alopecia in syphilis is loss of hair in ragged, angular patches, many and not large. Another form is general thinning out associated with seborrhea. Pigment changes on the sides of the neck occur—dark areas in which white areas are interspersed. Dactylitis is more frequently tuberculous than syphilitic.

The Vagus Reflex.—As long ago as 1870 Waller reported the history of cases of vomiting, of pain in the head and neck, of hysteria and of hemicrania, which were benefited by vagus compression. T. J. MAYS (Boston Med. & Surg. Jour., Jan. 16, 1902) has noticed in cases of phthisis that pressure over the course of the vagus on one side of the neck produces more pain than equal pressure on the opposite side, and that the supersensitiveness corresponds with the side of the chest having the affected lung. This writer believes also that such supersensitiveness is frequently a premonitory symptom of phthisis, and is often associated with other pulmonary and nervous disorders either as a forerunner or an accompanying sign. Cases of persistent paroxysmal cough are described in which this sign was present; these cases resisted the action of morphine, codeine, cocaine, strychnine, etc., but yielded to subcutaneous injections of a 2½-per-cent. solution of silver nitrate, introduced over the sensitive vagus nerve. The cure is believed to be due to the counterirritant action of the silver injections.

Pneumonia.—In the treatment of this condition it is important to remember that the chief element of danger is from the introduction of the pneumococcal toxins into the nutritional fluids of the body. E. F. WELLS (Jour. Amer. Med. Assoc., Jan. 18, 1902) recommends for the capillary paresis in ordinary cases calomel followed by salines, bleeding to the amount of 500 to 700 c.c., induction of free perspiration, free taking

of fluids, digitalis and adrenalin hydrochlorate in efficient doses. The value of the polynuclear leucocytes in combating the effects of the pneumococcus is probably without question, and to stimulate their increase when a satisfactory leucocytosis fails to appear he gives nucleinic acid, which may also, he believes, aid in preventing cardiac and vascular thrombosis. The ingestion of chloride of sodium is important and well salted food and frequent saline enemata are recommended. Early prophylaxis in diet and catharsis will usually prevent the uncontrollable fetid diarrhea which comes on late in some cases. Salol is a good intestinal antiseptic in such cases.

Blood-Examinations in Phthisis.—In order to throw additional light on the condition of the blood in phthisical subjects, L. Applebaum (Berl. klin. Woch., Jan. 6, 1900) divides his patients into groups corresponding to the stages of the disease. He finds that in the first stage of tuberculosis the blood-changes are not typical. In the type of patient in whom tuberculosis is a matter of years of slow development—the tall, pale, thin, rapidly-growing young subject with poorly-developed chest, anemia is present in the first stage of tuberculosis; the erythrocytes are diminished in number, the hemoglobin is reduced, the specific gravity is lessened and coagulation is delayed. In the class of individuals having good color and a liberal panniculus adiposis, the blood is absolutely normal during the first stage of phthisis. In the first group the toxic effect of a long-standing, but as yet not advanced tuberculosis, is apparent. In the second stage of phthisis the blood is apparently normal, estimated by the ordinary means for the determination of its characters. But autopsies show that the organs of patients dying during the second stage of phthisis are very markedly anemic. The fact is that there is a diminution in the blood mass—a loss of the watery element which conceals the true state of affairs by presenting normal findings when the formed elements are counted or the hemoglobin is tested. The main causes of the concentration of the blood in these cases are night-sweats and diarrhea. In the third stage of tuberculosis the anemia is no longer concealed under the mask of oligemia. During this period hemoglobin averages 40 to 45 per cent., erythrocytes 2 to 2½ million, specific gravity 1040 to 1042. The leucocytes are increased and may number 15,000 to 20,000 *sub finem vitæ*. In the hyperleucocytosis of the final stage the polymorphonuclear leucocytes are relatively increased and constitute 85 per cent. of the total number of white blood-cells.

NEUROLOGY AND PSYCHIATRY.

A Method of Treating Genuine Epilepsy.—Four stages or phases are included in the natural evolution of a case of true epilepsy. The first stage, says M. Lion (Berl. klin. Woch., Dec. 30, 1901), consists of the sum of minor anomalies which together form the "epileptic character." These anomalies include pathological irritability, sudden changes in mood, tendency to excesses and passionate outbreaks, unsocial instincts, unreliability in work. The second stage embraces innumerable shades of psychical disturbance, from the slightest momentary overclouding of consciousness to the more lasting and significant subconscious states, during which the patient may commit horrible crimes. The pauses in consciousness known as "petit mal" characterize the third stage; and finally come the typical epileptic convulsions. In the first two stages, Lion treated with rapid and extraordinary success twenty cases of long-standing epilepsy by means of the preparation produced in the laboratory of Professor Poehl and known as Cerebrinum-Poehl. This preparation he employed on theoretical grounds, believing that the disease is of toxic origin and that healthy nerve-elements possess an antitoxic power. Almost from the first day the anomalous psychical phenomena disappeared, to return either not at all or only after a long interval and then considerably modified. Stupid, passionate, aggressive, unsocial patients were transformed into more or less normal individuals. More advanced cases of both "petit mal" and "grand mal" were benefited in a notable degree; attacks became weaker, occurred at longer intervals and gradually tended to cease. In cases of unusual severity "opocerebrinum" was used in conjunction with sodium bromide.

Pupillary Alterations in the Insane.—In a previous article it was shown by De Montyel that scarcely one-fifth of a large number of insane subjects possessed normal pupils. In a third of the cases examined inequality of the pupils was present; in a large proportion disturbances of the light reflex or of accommodation were noted, and in a still larger proportion changes in the form of the pupils. Argyll-Robertson pupils were common; more rare was a loss of accommodation associated with normal reaction to light. Mydriasis was present in a larger number of cases than was myosis. In a new series of cases the same writer (Gaz. hebdom. de Méd. et de Chir., Jan. 5, 1902) has undertaken to study the evolution of pupillary abnormalities in the insane. It is shown that the disturbances are not transitory, but are lasting. The findings are regarded as valuable in the differentiation of insanity from general paralysis.

EYE, EAR, NOSE, AND THROAT.

Use of Gold Ball to Support an Artificial Eye.—In cases in which the eyeball has been previously removed and only a small stump remains, the difficulties of successfully fitting an artificial eye are many. In order to give better support and avoid incrustations behind and over the eye and also to prevent the sinister smile which a sunken eye gives, L. W. Fax (N. Y. Med. Jour., Jan. 18, 1902) devised the method of implanting a glass ball beneath the conjunctiva by a median incision and suture of the conjunctiva over the ball. Failures occurred in about thirty per cent. of cases on account of the breaking down of the suture line. Recently he has perfected the method by making an incision, from eight to fourteen millimeters long, obliquely across either the lower inner quadrant (right eye) or the upper outer quadrant of left eye. The conjunctiva is then separated from the deeper tissues and a gold ball inserted. Two sutures are used to close the wound. A conformer made of metal, the shape of an artificial eye with a hole in the center into which the ball fits, is then placed over the conjunctiva and the eyelids closed. The conformer is removed in twenty-four hours and the stitches on the third day. Thus the tension caused by the implanted ball does not come over the center of the eye and the tendency to expulsion is slight. The conformer temporarily holds the ball in place and the results are almost uniformly successful.

GENITO-URINARY.

Ulceration Into Rectum of Prostatic and Vesicular Neoplasm.—In critically examining the course of three cases, A. Guépin (Le Progrès Médical, Dec. 14, 1901) finds that ulceration into the rectum with the formation of a fistula which will permit the escape of urine is followed by great alleviation of the painful vesicular symptoms. In each case the prognosis, which up to that time had been grave, became more favorable and the patients lived for from three to five years. Strangely enough there was no propagation of the cancer along the rectal mucous membrane.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

DISEASES OF THE PANCREAS.

Diseases of the pancreas can no longer be said to be beyond the domain of hopeful diagnosis and of timely successful surgical intervention. The symposium on diseases of the pancreas at the meeting of the New York State Medical Society last week (see page 282) brought out in excellent relief the present status of our knowledge with regard to the physiology and the pathology of this important organ.

The advances which have been made in the study of pancreatic nosology and function have come from many sources in different countries. It is a matter of no little pride to be able to say that many of the important steps in the practical knowledge of pancreatic disease and its diagnosis, with the possibilities of successful treatment, have come from American workers. Since Senn's original monograph on the surgery of the pancreas in animals and the evident analogy with human beings that attracted world-wide attention, followed by Fitz's clinical observations on acute pancreatitis and by the work at Johns Hopkins in recent years accomplished by such successful investigators as Flexner and Opie, American investigation of pancreatic conditions has always been in the forefront of progress.

Some of the latest American observations are eminently suggestive and promise to be of great practical service. Flexner has confirmed Hlava's observations made at the Czeckish University of Prague with regard to the probable etiological rôle played by acid gastric contents in the production of acute pancreatitis. This disease occurs especially in alcoholic patients whose gastric juice is liable to be overacid. It was considered that the regurgitation of the gastric contents in such patients into the pancreatic gland through its duct might lead to acute inflammation of the pancreatic substance. Such a regurgitation is not impossible under the stress of the antiperistalsis that often accompanies severe vomiting. These conditions are especially liable to be fulfilled in hard drinkers. Flexner further has shown experimentally that the injection of artificial gastric juice into the pancreatic ducts is liable to set up acute pancreatitis.

Certain European observers point out the fact that an overflow of bile into the pancreas may take place under certain pathological conditions and that this is liable to set up acute hemorrhagic pancreatitis. When a biliary calculus lodges in the ampulla of Vater just within the duodenal papilla, through which the bile and pancreatic ducts open in common into the intestine, it is possible for the calculus to close completely the opening into the duodenum and yet not prevent all communication between the biliary and pancreatic ducts. As the bile is secreted under distinctly higher pressure than the pancreatic juice, it naturally finds its way up the pancreatic duct into the gland. From here it is absorbed and sts up irritative conditions. If but small quantities of bile find their way into the pancreas at intervals only a condition of chronic inflammation results. This gives rise to the induration of the head of the pancreas so often found during operations for gall-stones and which has frequently given rise to the suspicion of associated pancreatic malignant disease. If considerable bile finds its way into the pancreas, an acute inflammatory condition is set up which gives rise to the now classical symptoms of acute pancreatitis and which may be complicated by hemorrhage, fat necrosis, or eventually suppuration.

As to the treatment of pancreatic diseases the indications are much more clear than formerly. For acute hemorrhagic pancreatitis nothing can be done by surgical intervention. Expectant treatment must be the rule, though rather the armed expectancy of the surgeon in an appendicitis case than the helpless facing of a forlorn

hope. At the first sign of a purulent complication the surgeon must be ready to intervene. Dr. Park's expression is that the surgeon's position must resemble his attitude in an appendicitis case—"When in doubt, operate." Operation may save life. If pus has developed there is no other hope for the patient than in its prompt evacuation.

An important pathognomonic sign of pancreatic involvement seems to have been recently discovered by Opie at Johns Hopkins. He found in the urine of a patient dead from acute pancreatitis a fat-splitting ferment. This discovery has not been confirmed, because as yet no other cases of the affection have been under observation. Careful investigation of many other specimens of urine from living and dead subjects failed to reveal any trace of a fat-splitting ferment. It is well known that it is this ferment which causes the fat necrosis in acute pancreatic affections and its mode of distribution through the organism is as yet unknown, but it is thought at times to find its way into the urine and so might rather naturally be expected to appear in the urine. This may prove just the touchstone that was needed to differentiate such conditions as perforation of the intestines, intestinal obstruction and the rarer thrombosis of the mesenteric arteries from acute pancreatitis. The possibility of the occurrence of these conditions has always affected the certainty of the diagnosis of pancreatic affections.

On the whole we would seem to be entering on a period in the diagnosis and treatment of diseases of the pancreas that gives promise of adding another extensive province to the wide domain of abdominal surgery. The pancreas is nearly the last abdominal organ to yield to surgical advance, for already in several cases even the suprarenal capsule has been successfully treated surgically. We have every hope that the labors of American investigators will continue to throw more and more light over this important province of medicine and surgery. *Quod faustum vertat!*

CAUSE AND PROPHYLAXIS OF OLD AGE.

Old age is acknowledged to be a relative term. Some men are as old at forty-five or fifty as others are at seventy. We have accepted the expression "a man is as old as his arteries," but this furnishes very little information as to the causes of the senescence of the tissues that forebodes the near termination of existence.

Connective tissue changes in the arteries mean deficient blood-supply to the important viscera, for the arteries are an essential part of the blood-moving apparatus. There are many cases, however, in which the causes of the arterial degeneration are extremely obscure. There are not wanting good authorities in pathology who insist that arterial changes are always secondary to pathological conditions in important viscera, especially the kidneys. Certain families age very early in life and the definite tissue conditions, whose descent by heredity form the basis for the premature senility, are but very little understood.

Needless to say, the question is extremely interesting. There are many theories on the subject, but very little original observation. Dr. Mühlmann of Odessa, as the result of some recent investigations into the condition of the nervous system at various times of life, seems to have added distinctly to our scanty store of exact information with regard to the causes of old age. He has found as a uniform change from early life to old age a constant increase in the number of ganglion cells in the central nervous system which showed signs of fatty degeneration. In early youth very few of the ganglion cells give evidences of degeneration, although there are always some that have suffered visibly from the wear and tear of life. Until the number of degenerated cells nearly equals the healthy cells, life continues in its original vigor. The healthy cells seem able by their influence to compensate for their inactive or less active neighbors. When degeneration has gained the upper hand, that is, when the number of deteriorated cells exceeds that of the healthy ones, systemic decay begins.

This theory, supported as it is by a long series of observations, would seem to furnish rational answers to certain obscure questions. Longevity, for instance, is well known to be an hereditary or family characteristic. The intricate problem of heredity is simplified by the suggestion that the cells on which depend the essential legacy of vitality from generation to generation are not of many different kinds. A family propensity to longevity is dependent entirely on the cells of the central nervous system. This view is confirmed by our constantly widening knowledge of the importance of trophic influences in the maintenance of tissue vitality and even, as Prof. Pavlov has pointed out, in the accomplishment of organic function. There would seem to be in Dr. Mühlmann's work a further confirmation of the idea that the principle of life is in some manner more essentially and directly united to the nervous tissue and that vital impulses are distributed from this to other tissues.

The axiom "It is worry, not work, that kills" receives a new illustration from these conclusions. The importance of the nervous system for all functional derangements becomes very manifest. Physicians have realized from the very beginning of medicine how important mental states are in the therapeutics of disease. The reason for the influence of mind over matter has not always been clear. Now that we begin to realize how much of organic vitality and function is dependent on forces that originate in the central nervous system, the problem of the physical basis of mental influence loses some of its obscurity. Psychic conditions are essentially dependent on nervous tissues. Disturbances in the psychic sphere induce pathological conditions, not only in the cells that are told off for intellectual processes, but almost inevitably affect sympathetically other important groups of cells in the central nervous system with which they are intimately connected.

EARLY DIAGNOSIS OF TUBERCULOSIS.

The air in New York City has been full of discussions of tuberculosis in its various phases during the last few weeks. At least three medical organizations have devoted evenings to the subject. The monthly meeting of the local branch of the New York State Medical Association and the last stated meeting of the Academy of Medicine called for distinct contributions to the subject, some of which we have presented to our readers in the shape of the original papers, while full abstracts of the others, with the discussions they evoked, will be found in our society proceedings.

The practical conclusion of all the discussions is that the most important thing for the patient is very early discovery of his tuberculosis. To assure this, certain newer methods in diagnosis are recommended by specialists, though all are agreed that none of these new methods can be relied on with absolute assurance. The Roentgen rays, for instance, are in some cases of decided help very early in a case; not so much, however, by showing the actual location of an area of beginning consolidation as by demonstrating that there is a limitation of the excursion of the diaphragm. Very early in pulmonary tuberculosis at a time when the lesions can scarcely be said to have invaded the lung tissue proper, and when the inflammatory reaction is only peribronchial, Nature sets the affected lung at rest to a marked degree. By a nervous reflex, not well understood as yet, the half of the diaphragmatic muscle corresponding to the diseased lung is induced to limit its excursions. This phenomenon can be seen very clearly with the aid of the fluoroscope and, if there are any suspicions of the presence of tuberculosis, constitutes almost a pathognomonic confirmation.

It was pointed out by those who are expert in physical diagnosis that the Roentgen rays are not necessary in order to detect diaphragmatic inequality of movement very early in pulmonary tuberculosis. At a time when the ordinary physical signs give no sure basis for the diagnosis of tuberculous invasion and often serve scarcely to arouse suspicion, careful percussion of the base of the lung in full inspiration and full expiration will show not infrequently that the diaphragm fails markedly to descend on one side as compared with the other. Attention was also called to the fact that while inspection in front may show no difference in respiratory movement, inspection posteriorly may demonstrate easily recognizable lagging and limitation of respiratory movement. Finally, the Litten phenomenon, the actual observance of the excursions of the diaphragm, as it can be plainly seen through the thoracic walls of thin persons, and most tuberculous patients are favorable subjects in this regard, makes the recognition of unequal movements of the muscle on the two sides a comparatively easy matter. The Roentgen rays are then at least not indispensable for the very early diagnosis of tuberculosis in this way.

With regard to auscultation, Dr. Loomis called attention to a portion of the lungs important for the diagnosis of incipient tuberculosis that is not examined with sufficient care in routine practice. If the palm of the patient's hand be placed on the opposite shoulder the scapula moves outward and exposes the root of the lung to more facile examination. Here the breath sounds within the bronchi can be studied better than anywhere else. As the initial lesion in pulmonary tuberculosis consists of a thickening of the tissue lying in and around the bronchi the change in the breath sounds caused by this narrowing of their lumen and roughening of their surfaces can be detected very early. The prolongation and roughening of expiration over this area constitute very probably the earliest significant physical sign in pulmonary tuberculosis.

With regard to the use of tuberculin for diagnostic purposes, notwithstanding the favorable testimony of so conservative an authority as Dr. Trudeau, there is practical agreement that its use

is unjustifiable. In well-marked pulmonary tuberculosis it sometimes fails to give any reaction. When there is a history of syphilis the occurrence of a positive reaction has no pathognomonic significance. Dr. Otis of Boston, who has had probably more experience with the agent than any one else in this country, opposes its use. Many physicians have not only been disappointed, but have even seen unexpected acuity of symptoms follow its use. Dr. Janeway is not sure but in one instance of acute generalized tuberculosis brought to his notice the acute symptoms may have resulted from tuberculin injection at the hands of a preceding medical attendant.

There is a striking uniformity of opinion among experts in diagnosis that the physical signs in the lungs must not be depended on absolutely for the ultimate decision as to the presence of incipient tuberculosis. All of them lay great stress on systemic symptoms that confirm or even suggest the diagnosis. Undue rapidity of pulse is considered very significant. A rise in temperature of more than a degree during the day, Potain's symptom of lowered blood-pressure, as shown by a special manometer designed for the purpose, or loss of weight for which no adequate cause can be found, are all considered possible signs of the presence of tubercle that become positively diagnostic if only suspicious symptoms of doubtful significance are found in the lungs.

Practically all the authorities are agreed, too, that it is better to be safe than to be sorry. On even the suspicion of the presence of a tuberculous process, patients should be warned of their danger. Colds that "hang on" in spite of ordinary treatment and that show a certain absence of reactive vitality in the system are to be treated as if they represented an initial stage of tuberculosis. The diet and appetite are to be regulated, an abundance of fresh air and sunlight counseled, and patients should be recommended to limit trying indoor occupations as much as possible or to give up for a time exhausting physical labor. Of course, all this is for the well-to-do rather than the poor, but it represents the ideal of prophylaxis and therapeutics at a very early stage. In a word, the present idea among physicians is not to conceal the existence of tuberculosis from the patient as long as possible, as used to be done, but rather to warn the patient very early in the disease, perhaps even in the pretuberculous stage, and so arouse the reactive vitality of the system before it has been impaired by serious pathological conditions.

ECHOES AND NEWS.

NEW YORK.

Reception to St. Luke's House Physicians.—Dr. Beverley Robinson gave a private smoker last Saturday, February 1st, to the house physicians of St. Luke's Hospital who had served directly as house physicians under him. Dr. Robinson was made the recipient of a silver loving-cup.

City Isolating Consumptives.—Charities Commissioner Folks has ordered that all patients in the city's hospitals suffering from consumption be transferred to the new phthisis hospital on Blackwell's Island and that all such cases in the future be sent there for treatment. About thirty consumptive patients have already been removed from Bellevue. Those remaining will be removed as rapidly as possible. It is expected that the change will greatly lessen the death-rate in the city hospitals. The new hospital will shelter about 120 patients and two other buildings are in process of alteration. These will bring the total accommodation up to 350.

The Office of Coroner.—In New York City a growing disposition has recently arisen to question the further usefulness of this time-honored official. It is with no small show of reason contended that with the present administrative machinery the duties which usually devolve upon his office could be better performed in other municipal departments.

Bovine Tuberculosis.—At the meeting of the New York State Medical Society last week that body received from its Legislative Committee a recommendation that the questions involved in Dr. Koch's paper at the London Tuberculosis Congress upon the communicability of bovine tuberculosis invited further experiments in this field before any conclusions could be drawn that would modify existing methods for dealing with the disease. The recommendation was also made that local boards of health be requested to follow the work of the Milk Committee of the New York County Medical Society in the efforts made to protect that commodity. The Committee's report also favored indorsing the movement for the establishment of a National health board with a representative in the President's Cabinet.

Damages to the Manhattan Eye and Ear Hospital.—No building in the vicinity of the recent explosion which occurred in the construction of the Subway suffered more than the Manhattan Eye and Ear Hospital. Practically all of the glass in the building was shattered, most of the plaster was ruined and much of the woodwork and ornamental coping in its front was dislodged or broken. It is now reported that the building inspectors have declared the institution unsafe for occupation at present. The Managers have displayed remarkable courage and energy in their efforts to repair the damages and restore the hospital as rapidly as possible to its normal condition. No similar charity is of more benefit to the city and every assistance in rehabilitating the institution should be extended to its management.

PHILADELPHIA.

Hospital for Mt. Pocono.—A Women's Auxiliary of the Pocono Protective Health Association has been formed with Mrs. William R. Fisher as president. The objects of the Association are the erection, equipment, and maintenance of a small hospital building for emergency cases in the immediate vicinity, for either residents or summer patients and guests. Treatment will not be free. Work on the building will probably be begun in the spring.

Large Increase in Typhoid Cases.—For the week ending February 1st there were reported 201 cases of

typhoid fever and 21 deaths, an increase of 84 cases over the previous week. Only six wards in the city are free from the disease, the West Philadelphia wards, as last week, showing the larger number of cases. The one explanation for the increase in cases and deaths is given by the Bureau of Health as polluted drinking water; the one safeguard is to boil the water. Circulars insisting on the latter precaution are being distributed.

Camden Charities Imposed Upon.—Managers of the Cooper Hospital and the Camden City Dispensary have lately made an investigation of the circumstances of applicants for free treatment at those institutions. A twenty-day examination showed that of eighty cases applying at the hospital, twenty were in a position to pay for treatment and of ninety-six cases at the dispensary thirty should have been debarred from free assistance. The investigation is the first step toward preventing such imposition.

Dr. Hare's Unpleasant Experience.—Dr. Hobart A. Hare had a few hours' unpleasant experience during the past week as the result of a mistake made by a zealous member of the police force. Dr. Hare, accompanied by an expert, was testing a new automobile and while on South Broad Street was preceded by another party who exceeded the required limit of speed. On his return the doctor was placed under arrest as the offending party, taken to Moyamensing Prison and conducted to a cell after being refused telephonic communication with his family and counsel. Friends soon after secured his release. An investigation now being conducted is likely to result disastrously for the officers responsible for the indignity.

Death of Dr. Charles H. Burnett.—Dr. Charles H. Burnett, the distinguished aurist, died at his residence in Bryn Mawr, January 29th, of pneumonia. Dr. Burnett was sixty years of age, a native of this city, and a graduate of the Medical Department of the University of Pennsylvania, the degrees of A.B. and A.M. having been taken at Yale. He served as a resident at the Episcopal Hospital in Philadelphia and later studied optics and diseases of the ear in Vienna. He was a member of various medical societies in Philadelphia and professor ot otology at the Philadelphia Polyclinic and School for Graduates. Dr. Burnett edited an encyclopedia of diseases of the ear, nose and throat, and last year completed a text-book on diseases of the ear.

Meeting of Antivivisection Society.—The American Antivivisection Society held its nineteenth annual meeting in this city January 30th. The President, Dr. Matthew Woods, was re-elected. The President, in giving an account of vivisectional experiments which he claimed were to be found in nearly every medical periodical, mentioned the connection of hydrophobia with them. He stated that he had been looking for twenty-five years for a true case of hydrophobia and as yet had not found it. Neither had he found a physician who had seen a genuine case. The Society states that it is important that the public mind should be disabused of the popular fallacy that hydrophobia is a common disease.

"Cut-Rate" Druggist is Upheld.—The question whether or not the maker of a proprietary medicine can impose upon a purchaser a contract determining its price and thus prevent "cut-rate" selling, recently came up for argument in Common Pleas Court. The suit was brought against a local druggist by Julius Garst of Worcester, Mass., who sued for $105, a fine of $21 for each offense. The Court holds that it will not recognize a condition on a package of medicine providing for its sale at not less than a stated price. There is no averment that the defendant ever agreed to the terms of the notice. The plaintiff by printing a notice on the box attempts to make a contract with each person accepting a box, whether that person assents to it or not. The opinion is that the notice on the box has no contractual power whatever.

Serious Accident to Physician.—Dr. Raymond J. Harris, a demonstrator in chemistry at Hahnemann College, was possibly fatally injured February 1st as the result of a collision between his carriage and a hook and ladder truck. A fracture of the skull was sustained and, although the last reports are favorable, his chances for recovery are considered slight.

Removal of Superior Cervical Ganglion of the Sympathetic.—At the Jefferson Hospital Clinic, February 1st, the left superior cervical ganglion of the sympathetic nerve was removed from a patient by Dr. W. Joseph Hearn assisted by Dr. J. Chalmers DaCosta. The man is a patient of Dr. George E. De Schweinitz and has been suffering for some time from chronic glaucoma. The right ganglion was removed at the Philadelphia Hospital by the same operators on December 20th. While no distinct improvement in the corresponding eye has been noticed, the process has apparently, been stopped and the eye is getting no worse at least. So far as known these are the first operations of the kind done in this city.

Many Bequests to Charity.—By the will of the late J. Alfred Kay many hospitals are the subjects of substantial bequests. Among these are $5,000 each to the Pennsylvania, Germantown, University, Jefferson, Orthopedic and Polyclinic Hospitals. The codicil also gives $1,000 each to St. Agnes', St. Joseph's, Jewish, Hahnemann, Presbyterian, German, Children's, Howard, Medico-Chirurgical, and Gynecean Hospitals and to a number of homes for the blind, etc.

Philadelphia Neurological Society.—At the monthly meeting, held January 28th, Dr. William G. Spiller exhibited a case of paralysis of the face and upper and lower limbs on the right side and of the tongue and muscles of mastication on the left side. The patient had been in fairly good health until one year ago, although she had had three miscarriages. The attack was preceded by drowsiness and headache. The lesion was supposed to be specific in nature. Dr. Spiller stated that he had noticed paralysis of the muscles of mastication in three cases of hemiplegia. He also exhibited a patient to illustrate tests for differentiating between true hemiplegia and malingering or hysteria. One is the contracture of the anterior tibial muscle when the thigh and leg are flexed, the phenomenon being caused by the contraction of the iliopsoas muscle. Another is the extension of the great toe when the leg is raised, this indicating impairment of the motor tract.

Dr. M. H. Bochroch exhibited a patient showing superior tabes. The history and condition of the case suggested paresis with beginning tabes of the cord.

Dr. Charles S. Potts exhibited a case of progressive muscular atrophy (Aran-Ducheame type) in which the atrophy began in the extensors of the hand and fingers.

Drs. A. P. Francine and D. J. McCarthy exhibited a case of facial tic in which each contraction is followed by complete paralysis in the facial and hypoglossal distribution on the same side. Discussion of the case led to the general conclusion that the lesion was a small cortical one in the facial area.

Dr. F. Savary Pearce reported a case of poliomyelitis with increased knee-jerk.

Dr. A. Buckley, by invitation, read a paper entitled "Carcinoma of the Spine, with Autopsy" and showed microscopical specimens.

Academy of Surgery of Philadelphia.—At the meeting of February 3d, Dr. De Forest Willard showed

a case of intestinal anthrax reported at the last meeting.

Dr. Edward Martin read a paper on Intestinal Suture.

Dr. G. G. Davis read a paper describing the radical cure of hemorrhoids without general anesthesia. The operation is done by the cautery under cocaine anesthesia. The diseased area is exposed by a speculum, preferably the Kelly instrument, and cotton saturated with a four-per-cent. solution of cocaine introduced. The tube is withdrawn, leaving the cotton in place. After a short interval the cautery knife is used, puncturing, burning superficially, or deeply as desired, being careful not to get too high up, thus avoiding hemorrhage. Another plug of cotton is introduced and left in until passed with the first bowel movement. Only one portion of the hemorrhoids is removed at a time, the others following at intervals of at least a week. Dr. W. L. Rodman spoke of a case recently operated upon by him, the man refusing to take anesthetics of any sort and standing the operation very well. Speaking of the danger of general anesthetics in rectal cases he stated that operations on the rectum, genitalia, or matrices of nails require the third degree of anesthesia to abolish sensibility. This made them more dangerous than other more important operations for which only the second degree of anesthesia is needed.

CHICAGO.

X-ray Machine for Cook County Hospital.—To facilitate the work of the Cook County Hospital medical and surgical staffs, Warden Healy has ordered the purchase of an X-ray machine for that institution. The X-ray machine will not cost less than $550.00.

For a Children's Hospital.—A subscription dance will be given February 5th, the proceeds to be used toward building a hospital for sick children in connection with St. Joseph's Orphan Asylum.

Insane of the City.—During the year 1901 the detention hospital received 1,503 patients, who were distributed as follows: Cook County Asylum, Dunning, 667; Illinois Northern Hospital, Elgin, 293; and Illinois Eastern Hospital, 166. The remainder, about one-third, were discharged.

Exclusive Medical College for Women.—Will Chicago have a high-grade medical college solely for the instruction of female students? This question, based on rumors of plans of founding such an institution by the Alumni of Northwestern University, has deeply stirred the medical and college circles of the city. It is thought that Dr. Eliza H. Root, Dean of the Woman's Medical School of the Northwestern University, which has just been sold, is at the head of a movement to organize such a school. Associated with her in the planning of it are reported to be Mrs. E. L. MacEwen, Mrs. John Ridlon (wife of the noted orthopedic surgeon), and Mrs. Martha F. Crowe, all of Evanston. Plans and ideas in connection with the proposed school have been talked over. It is said that the Alumni were unanimously of the opinion that they should keep together and in their unity is seen a powerful factor for the support of the school if it is founded. The question now comes up in connection with the opening of Rush College to women and the permanent coëducative feature of the College of Physicians and Surgeons. Will the Northwestern admit women to its medical school, or will it throw out coëducation altogether and be the great university for men only of the West? These questions are declared by physicians who are watching the checkerboard of educational enterprise to be paramount issues, affecting the status of Western women in regard to opportunities for learning and having a marked influence on the suffrage question itself.

Chicago Health Department.—An effort in preventive medicine on a scale of considerable magnitude was inaugurated last week by the City Health Department. Its field is an area of some 600,000 square miles of territory in the ten States of which Illinois is the southern center and the remotest boundaries of which are within a few hours' railway travel of Chicago. Among the 25 millions of people living in this area the number of cases of smallpox has increased more than 900 per cent. since the first of the year, over the number reported during the corresponding period of 1901. That is to say, between December 28, 1900, and January 24, 1901, there were only 1,070 smallpox cases reported in this territory while during the similar period ending January 24, 1902, there were 10,820 cases reported—an increase of 911 per cent. Authentic information, gathered by wire and mail, from State and local health authorities and from personal investigation by the contagious-disease experts of the Department—sent to a number of infected localities most directly menacing Chicago—convinced the Health Commissioner, Dr. Reynolds, that the disease is still spreading unchecked, that it is not being fought intelligently or adequately, and that its continuance seriously threatens not only the public health, but the material interests of this vast area by the certainty of "shot-gun quarantines" sooner or later and consequent costly and vexatious interference with travel and traffic. These views were presented at a conference with the representatives of the leading railways centering in Chicago and their coöperation with the Department was urged in a concerted effort to "stamp out" the pestilence. Ready assent was given, the necessary men and means were assured and it is confidently believed that the situation will be well in hand within a fortnight after operations are begun. The plan contemplated wholesale vaccination and revaccination in every infected locality; the provision and maintenance of suitable isolation hospitals where necessary; thorough disinfection of smallpox premises and belongings; strict inspection of all persons offering to travel from infected localities and refusal to carry those who do not comply with the requirements. This is the measure relied on to control the objectors, "conscientious" or otherwise, and is one fully within the power of the railways to enforce. Special attention will be paid to the condition of employees in manufacturing establishments—particularly those of textile fabrics—and the railways will set the example by still more rigorously making recent vaccination a condition of further employment. Competent vaccinators and supplies of pure, tested vaccine lymph will be furnished gratis in all proper cases. The work along each railway line will be under the direct charge of the medical director or chief surgeon of the company and a central office will be maintained in the city for the receipt of reports, requisitions, etc., from those engaged in the campaign. Dr. Reynolds has volunteered to take charge of the central office. This action is not taken solely or even chiefly in the interest of Chicago. The situation here has never been alarming at any time during the three years of the epidemic and at the close of last week there were but 21 smallpox cases in the Isolation Hospital—5 having been received and 7 discharged during the week.

There was an increase of 37 in the number of deaths last week over those of the week before—chiefly from the acute intestinal, heart and nervous diseases and from consumption, penumonia and scarlet fever. Influenza is still very prevalent and, although of a mild type in itself, it mischievously and often fatally complicates many other maladies. It is feared that the cur-

rent month will not make as good a record as January, when the total deaths, 2,229, furnished a midwinter death rate of only 14.42 per thousand of population, or nearly four (3.9) per cent. less than the rate of January, 1901.

CANADA.

Deserting Her First Love.—Princess Sophie Bamba Dhuleep Singh, daughter of the Maharajah of Lahore, India, is leaving the Northwestern Women's Medical College, Chicago, where she has been a student in medicine and will throw in her lot with the Women's Medical College, Toronto.

Fever Following Smallpox.—While the unorganized districts of Ontario are becoming cleared of smallpox the pest is securing a firmer hold upon the settled and older districts of the Province. Scarlet fever and diphtheria are raging in the lumber camps to the north where the smallpox has been prevalent. Both diseases seem to be of a very malignant type.

County Health Inspectors.—The attention of the Ontario Legislature is being called to the Medical Health Act with a view to securing amendments thereto which will provide for the appointment of county instead of township medical officers of health. At present each township appoints its own health officer at the nominal salary of $50 to $100 per annum and very often the duties of these officers are perfunctorily performed. Better service could no doubt be secured if county officers were appointed with an adequate salary.

Notices in Hospitals for Pay Patients.—During the past week a Toronto physician has been seeking to recover from the executors of an estate the amount of his bill for services rendered a patient during the lifetime of the latter. The executors refused to pay on the ground that the physician was on the junior staff of the hospital at the time the services were rendered in the hospital. The judge, who was on record before in this matter of charging hospital patients, stated it would be wise and fair for the hospital authorities to post up notices in all such institutions stating the conditions under which patients are charged for doctors' attendance. The suggestion seems to be a good one.

Blackmailing Doctors in Toronto.—Two Toronto physicians have been subjected to what the Crown Attorney states to be nothing more nor less than attempts at blackmail. One doctor was called to attend a citizen's wife and another, a specialist in diseases of children, to look after the health of the child of a family, which had recently arrived here from New York. In both cases the doctors were held up by the husband on account of alleged insults to the virtue of his wife. The former doctor laid a trap and caught his would-be blackmailer; the second gave him the option of walking out of his office or being thrown out. The case is being ventilated in the Police Court.

Hospital Quarantined.—Smallpox of a mild type appears to be spreading in Montreal, and it is quite a common occurrence for people to be walking in to the Health Department afflicted with the disease. Notre Dame Hospital has been quarantined, one of the servants having been attacked by the disease. There are two hundred patients in the hospital at the present time and they will have to stay there until February 12th.

Southwestern Manitoba Medical Association.—This Association was organized only a few months ago and out of the seventy available medical men in that section sixty-seven have already become members and it is expected the others will do so shortly. An effort is to be made to organize the whole profession in the Province of Manitoba. A new tariff for insurance companies and lodge work has been agreed upon and every member of the Association has signed a pledge binding them to this tariff from January 1, 1902. Fraternal societies with insurance will be charged $3.00 per examination; insurance companies, $5.00. A provisional tariff of fees has also been arranged to which all will adhere as closely as possible. The members of the Association have also decided to render statements of accounts at least quarterly. The Association discourages lodge practice.

Samaritan Hospital, Montreal.—There are fourteen patients in this hospital at the present time, of whom eight are being treated free. Dr. Leslie Allan of Point St. Charles has been promoted to be chief anesthetist in place of Dr. Leprohon, resigned, and Dr. F. W. Harvey has been appointed assistant anesthetist to succeed Dr. Allan.

Penitentiary Hospitals.—The Inspector of Canadian penitentiaries has handed in his report to the Minister of Justice for the past year. On June 3d last the population of these institutions throughout Canada numbered 382 as compared with 1,424 on the same date in the previous year. There were twenty-three deaths during the year. Referring to the St. Vincent de Paul Penitentiary, the Inspector reports that during the year one hundred and fifty pounds of tincture of opium and about ten thousands morphine pellets passed through the dispensary. This fact gives reasonable ground for the opinion that the administration of this department of the prison is characterized by imprudence and extravagance. The health of the convicts in this institution has not been considered at all satisfactory, and it is thought to be traceable to the overdrugging with opiates.

GENERAL.

Smallpox in London.—A recrudescense of London's smallpox epidemic was apparent last week when 71 cases were reported in one day.

Academic Honors.—Professor Kossel, who holds the chair of physiology at Heidelberg, has been elected a member of the Stockholm Academy of Sciences.

Medical School for Indo-China.—The government of Indo-China has decided to establish a medical school at Hanoi. The direction of the school will be entrusted to Dr. Yersin, who will have two assistants.

Bacteria on Money.—Dr. Vincent, through bacteriological investigations made at the "Hôpital du Bey at Algiers, has found that almost all varieties of bacteria occur upon currency, but most common are the germs of suppuration. Bacteria are, however, comparatively short-lived upon metal currency, the metal having a certain antiseptic effect; the action of gold is less marked in this respect than other metals. The bacillus typhosus will live for from five to seven days upon a gold piece, but dies in less than eighteen hours upon other metals.

First Sicilian Medical Congress.—This Congress will be held at Palermo in April, 1902.

French Scientist's Discovery.—At a meeting of the National Society of Physicians at Lyons, Dr. Lepine announced that he had isolated from the urine of pneumonic patients a crystallizable substance, the study of which he believes will give the key to the pathogenesis of diabetes. This substance *in vitro* prevents glycolysis in the blood, so that, if it is not eliminated or destroyed the blood becomes surcharged with glucose. The theory advanced is that although in pneumonic patients this substance is eliminated, normally it is destroyed by the pancreas; hence the pancreas does not elaborate a glycolytic substance, but in its normal state destroys an antiglycolytic substance which is always present in the blood.

Consolidation of Medical Journals.—An event significant of the tendencies of the time has just occurred in Cleveland. Plans for the amalgamation of

the "Cleveland Journal of Medicine" and the "Cleveland Medical Gazette" have been brought to a successful issue. On January 20, 1902, was held the organization meeting of the "Cleveland Medical Journal" Company, which is composed of those physicians now interested in the two old journals, together with a good proportion of the representative physicians of Cleveland, numbering in all 45 stockholders. At a considerable sacrifice on all hands the two old journals have been transferred in their entirety to the new company that will publish the "Cleveland Medical Journal," which is to be an independent and free professional institution conducted for the good of the medical community with no idea upon the part of the stockholders that they shall ever look for dividends. At this meeting a temporary organization was formed, consisting of Dr. Marcus Rosenwasser, President; Dr. William E. Bruner, Secretary; Dr. Joseph F. Hobson, Treasurer. Dr. P. Maxwell Foshay was elected editor and Dr. Edward S. Lauder associate editor.

Hydrological, Climatological and Geological Congress.—This Congress will be held at Grenoble, France, in October, 1902. Among the subjects to be discussed are: Action of Mineral Waters on the Tissues; Hydro-Mineral Treatment of Phthisis, of Diseases of the Stomach and of the Skin; Bacteriological and Chemical Examination of Mineral Waters; Influence of Heat, Cold, and Altitude upon Respiration; Necessary Meteorological Conditions in the Establishment of Sanatoria; Open and Closed Sanatoria.

Another Million for Harvard Medical School.—Last June J. Pierpont Morgan agreed to erect, at a cost of more than $1,000,000, three of the buildings required for the accommodation of the Harvard Medical School. President Eliot recently announced to the Medical Faculty that John D. Rockefeller proposed to give $1,000,000 in furtherance of the same project, provided other friends of the University would raise a sum of money in the neighborhood of $500,000, to be used by the medical school for land, buildings, or endowment. It was stated that this condition would doubtless be speedily complied with. Since the announcement that Mr. Morgan was to erect three of the buildings the plans of the architects have called for two additional laboratory buildings, and a considerable fund is also needed to provide for the increased running expenses of the school. It is therefore especially gratifying that Mr. Rockefeller's gift makes it possible to complete the plan which will give this country a great medical university, equal and in many respects superior to any at present existing in the world. It was largely through Dr. W. B. Coley of New York that the gift was made. He laid before Mr. Rockefeller the urgent needs of the university, and it was he who notified the Medical Faculty and President Eliot of the gift.

Dr. Trudeau in Florida.—Dr. E. L. Trudeau of Saranac Lake, N. Y., is now at Palm Beach, Fla., where he will remain for several weeks to enjoy the climatic contrasts to the Adirondacks.

Syracuse Hospital.—At the opening exercises of the new Hospital of the Good Shepherd in Syracuse on February 5th, it was announced that through the goodness of Mr. W. B. Cogswell the Hospital would receive one hundred thousand dollars in cash. It had also been arranged by Mr. Cogswell that the interest on another hundred thousand dollars borrowed would be paid. This money will be expended in enlarging the hospital.

The League of Human Life.—The lay press of Paris, France, led by the "Matin," has undertaken an apparently much-needed reform in sanitary matters. First, the water supply said to have been derived from the polluted Seine was attacked; later the adulteration and manufacture of drugged wine was investigated, and now the pure-milk question is to receive attention. The "Matin" announces its intention of forming a league, to be called the League of Human Life, the object of which will be to analyze the milk brought to it by its members and to prosecute in the name of the league any and every milk dealer thus discovered to be dealing in impure milk. Already it has secured the support of many of its readers, and it will not be long before the league will be ready for business, when for the first time in its history, perhaps, certainly for many generations, the French capital will be on the way to a supply of milk as it comes from the cow. Now that a start has been made, it is expected that the newspapers of other cities will enter into the new field of usefulness opened to them.

The New Lunacy Bill for New York.—On Wednesday the bill that proposes among its other retrograde provisions to wrest the management of the State Hospitals for the Insane from the authority of the present local boards passed the State Senate by a vote of 31 to 18. On the same date but previous to the legislative action, President George F. Canfield of the State Charities Aid Association sent the following telegram to Gov. Odell:

"In behalf of the State Charities Aid Association and Committee of Twenty, representing charitable organizations of city and State, I respectfully request that hearing be granted before you affix your signature to Lunacy Bill, should it reach you, with one week's notice of date of said hearing."

Since this bill has received the continuous support of the Governor, it is scarcely probable that he will long refrain from making it a law.

OBITUARY.

John T. Metcalfe, M.D.

On the 30th of January, 1902, Dr. John T. Metcalfe, for many years a medical practitioner of great eminence in the city of New York, departed this life in the eighty-fourth year of his age in the city of Thomasville, Ga.

He was born in Natchez, Miss., was the eldest child of Dr. Metcalfe, who in early life was a practitioner of medicine and in later years a planter, living upon the plantation known as Montrose, lying upon the banks of the Mississippi not far from the city of Natchez.

Arrived at the appropriate age, the subject of this sketch entered the Military Academy at West Point, graduated with distinction, and served as lieutenant of ordnance during the war with the Seminole Indians, who, having retreated to the Everglades of Florida, made a determined resistance to the authority of the United States. Exposure to the malarial influences of Southern Florida affected his health very badly, and influenced either by this fact or by a distaste for the life, he resigned from the army and commenced the study of medicine, for which he had had, even from his boyhood, a decided fancy.

Graduating from the University of Pennsylvania, that grand old school which so many eminent physicians throughout the United States have proudly hailed as Alma Mater, he went to Europe and studied in the schools of France, Germany, England, and more especially of Scotland. Returning to this country, he came to New York and married Augusta, a daughter of Christopher Collis of that city and began the practice of medicine.

Nothing could have exceeded the kindness and cordiality of his reception by the physicians of the city of his choice. He was received with open arms by its

representative practitioners, such as F. U. Johnston, Alonzo Clark, Parker, Delafield, Markoe, his old army chum, William H. VanBuren, and many others, whose kind interest soon put him in possession of a promising practice.

On his side he was possessed of so many personal advantages which increased the inherent value of those put at his disposal by his friends that there was no wonder that a brilliant, rapid, and most gratifying success declared itself in his favor. His personal appearance was most attractive, his manner most engaging and captivating, his conversational powers quite remarkable, and his education, both general and professional, of the highest type within the reach of the men of that time. He spoke French so fluently that it was always the language of his household; he was quite familiar with German and to a more limited extent was acquainted with Italian. Add to these advantages in social life the fact that his kindness of heart and thoroughness of medical education united in making an able and attractive physician, and one is prepared to accept the result, one of the largest and wealthiest practices, after a very short period of waiting, that New York has ever known.

He soon became professor of the institutes and practice of medicine in the University Medical College, physician to Bellevue Hospital and consulting physician to institutions too numerous to mention.

Men of experience always suspect such sudden and brilliant successes as having within them the elements which insure early decay. But Metcalfe's career belied such ill-omened suspicions and such gloomy prophecies. His sudden and rapid success was sustained by true merit, strict honesty of purpose, and the possession of traits of character which endeared him to all who knew him. "Never," it has been declared over and over again by those who were honored with his intimacy, "have we ever met with any one who possessed such hosts of frends and so small a number of enemies."

John T. Metcalf, M.D.

But there were two sad influences which gradually worked against him and in time cut short his wonderfully brilliant career. Within a few years he lost a wife upon whom he leaned for counsel, for happiness and for comfort. Then the hand of death removed, one after the other, six out of seven children; some of them in early life, some after marriage. Later in life he married Susan, the daughter of William Whitlock of New York, but after comparatively few years of married life she too was taken from him. None but those familiar with the tender, gentle, affectionate heart of the man could appreciate the nature and degree of his suffering. Had not God in His mercy left him a de-

voted son, who, relinquishing his career in the United States Army, has spent his life in ministering to him, no one could have predicted the result.

Then his health entirely failed him; he became a terrible sufferer from the worst form of gout; and in about his sixtieth year he was forced to give up a profession of which he was so brilliant an ornament, upon which he shed such luster, and in which he was able to do so much of good, both for patients and for brother practitioners.

The theme is so fascinating a one to him who writes these lines that he is obliged to force himself to come to a conclusion, although dissatisfied with the brevity and insufficiency of this short and imperfect sketch.

" Lo! through a storm of blinding tears I see
The rainbow vision of his noble life:
True heart! brave soul! Ye are not dead to me,
But live to hold God's beacon in the strife!"

—T. G. T.

BYWAYS OF MEDICAL LITERATURE.

Prophylaxis of the Sequelæ of "Wild Oats."

Family physicians are often approached by fond mothers with the idea that they may be able to provide suggestions by which the sons of wealthy families may be kept from the health-destructive influences liable to follow a crop of wild oats too injudiciously sown. The suggestion of an editorial writer in the *New York Independent* for December 26, 1901, may prove helpful to physicians in this matter. He recommends "dissipation by machinery." He says that M. Santos-Dumont showed originality by racing an airship around the Eiffel Tower instead of racing horses in the Bois de Boulogne. This is a new form of dissipation which, on account of its comparative innocuousness and possible benefits, may be commended to the attention of gilded youth everywhere. Balloon racing over the sea and land is likely to become fashionable among young men who have the spirit of adventure and the money to back it. The era of aero-automobolism can not be developed unless somebody puts a good deal more energy and money into it than is going to pay. And as for danger, well, science must have its martyrs and a community can spare the idle sons of rich men as well as any other class.

"The example of the Duke of the Abruzzi in sowing his wild oats in 86 degrees 33 minutes north latitude, instead of in Vienna or Paris, is well worth the attention of royal families. How much better it would have been for Edward VII. if he had spent his lengthy adolescence in the Arctic regions instead of at house parties in Merrie England. There is so little for princes to do nowadays that it would be well to keep them in cold storage, safe from anarchists and actresses, until they are needed."

These suggestions will surely be of prophylactic importance for the sons of our millionaire kings of finance, commercial potentates, coal barons, etc. No higher object in life than the development of applied science could well be imagined. The taste for this sort of thing is expensive, but not more so than a taste for exploiting the virgin forests of the vaudeville stage, and it is physically much less dangerous. Besides, there is an air of distinction about scientific experiment, due to the fact that but few have entered the field, that should prove a powerful source of encouragement.

Curious Transformation of Medical Terms.

There are some very interesting reflections on the changes in signification that medical terms have undergone during the course of centuries, in a recent philological work called "Words and Their Ways in English Speech." The word treacle, for instance, which was formerly a medical term, but now means only a syrup, is a typical example of word transformation. Treacle is derived from the Greek, theriakon, which means pertaining to a wild beast. From this it came to mean a remedy for the bite of a wild beast, then its signification broadened to that of antidote for anything harmful. Finally, its signification developed to that of a remedy of any kind; as most of the old remedies were syrups, the modified theriakon, that is, treacle, came to mean simply a syrup. In the sense of remedy treacle occurs in a well-known passage of Chaucer, who speaks of the Lord as the "treacle of every harm," that is, a sovereign remedy for every grief. A writer in the *New York Saturday Times Review* calls attention to the fact that the authors of the book might have well referred here to the famous Treacle Bible, which obtained its name from its rendering of a well-known passage as follows: "Is there no treacle in Gilead?" The modern word balm, also, by the way, a medical term, has come to replace treacle in this passage, though its philology does not give it a much better right to the place. It is only a modification of the word balsam, originally the pitchy product or inspissated sap of trees or plants.

The Pathology of Gambling.

A recent work by a very well-known Italian authoress is really a clinical study of the pathological side of the gambler's life. The book "The Land of Cockayne," by Matilda Serao, is a study of local conditions in Naples, the birthplace of the talented authoress. All the essential unhealthiness of the mental state of the gambler's mind is brought out. People of every condition of life, from the lowest to the highest, are represented as the victims of the passion. It is evident that any true reasonableness is not present in the great majority of those whose life tragedy it brings about. We have come to acknowledge that the man who thinks he has attained perpetual motion is not sane. Some time there will be just as general an acknowledgment that the man who thinks he has found a way to beat the game, a new and ingenious system by which he is sure to win from professional gamblers, is not in his right mind. The delusion that it is possible to best the gamblers at their own game or that somehow luck is bound to come sooner or later, is one of the most common in our modern life. It replaces many of the superstitions that we condemn so heartily in former generations. Not all of these superstitions are extinct, however, and one of the merits of Matilda Serao's book is that she shows how the gambler's mind is attuned also to the reception of any form of superstition that may with even far-fetched plausibility seem to promise luck.

Undoubtedly a time will come when it will be realized that a man under the influence of an uncontrollable passion for gambling is as much a sufferer from mental disequilibration as a sufferer from any other form of irrational emotivity. The medical profession are agreed that the habitual inebriate needs to be put under control for his own benefit. Our law-making is trending in this direction in many States. The gambling habit will come to be recognized as the result of an imperative impulse of the same nature for which not calm reasoning but positive control is required. The realistic treatment of such a theme is a distinct popular medical document, for it hastens the foundation of a healthy public opinion in the matter.

The Nobel Foundations and Awards.

The recent award of the Nobel prizes for the first time arouses curiosity in the man and his work. There

is an informing article on him in the *Westminster Review* for December. Nearly every one knows the paradox of his career. He spent his life in making high-grade explosives and incidentally accumulated a fortune of $10,000,000. At his death he willed the income of this ten millions of dollars to be given mainly for prizes that are to promote the interests of peace. One of the prizes is to be given every five years to the man or the Society that has done most to promote universal peace among the nations. The other prizes are given, as is known, for the greatest recent discoveries in medicine, in physics and in chemistry and for the most significant work in literature.

Nobel's was a dominant personality. As the result of his life work, the writer of the article in the *Westminster Review* says, the Swedes as a nation have come to take a special interest in the manufacture of explosives. "Just as a German student devotes his chief attention to bacteriology, or an English chemist to mineralogy, so will a Swede make the science of explosives his primary study."

The writer insists that the clauses in Nobel's will are no real irony upon his actions during his life-time. Like a surgeon of daring he sought to excise the cancer of war by using the most dangerous instruments, since none other could be effectual. The arrangements made for the distribution of the prizes seemed to be the best possible to secure absolute impartiality. In this Nobel's business instincts and habits are especially observable. The awards of the prizes for the first time have given universal satisfaction, with the possible exception of that to Professor Behring for the greatest recent discovery in medicine. There are many who think that Professor Behring's position in securing a patent on his invention in order to reap the benefit of it for himself should preclude him from award for humanitarian advances made. Perhaps, in the light of certain recent accidents with diphtheria serum, Professor Behring's own plea in this matter will be listened to with more attention than formerly. He has always insisted that his only object in securing the patent on diphtheria serum was to prevent the putting on the market of inferior and perhaps harmful products out of which the conscienceless would make large amounts of money, while the development of the great idea underlying antitoxin would be delayed perhaps for many years.

MEDICINAL SEDATIVES IN DISEASES OF THE NERVOUS SYSTEM—LEGAL PUNISHMENTS AND PSYCHIATRY—UNUSUAL FORMS OF PARALYSIS—ANGINA, RHEUMATISM AND ERYTHEMA NODOSUM—MEDICAL AND SURGICAL CONDITIONS IN PEKIN.

KREUSER (Schussenried), at the thirty-second annual congress of the Southwestern German Neurologists and Psychiatrists, read a paper on the value of medicinal sedatives in the treatment of diseases of the mind. After a short review of the recent developmental process in the treatment of diseases of the mind, with a special view to the causes of the disease within the nervous system itself, he endeavored to draw an analogy and to show, from the results of physiological experiments as to the signs and time of exhaustion, at what period medical aid should be given in order to be of value. Of the ordinarily employed means to this end, in addition to ordinary attention to the fundamental principles of psychiatry, the best and foremost means of treatment are rest in bed and the better methods of hydrotherapy. In addition to this, however, there are other means which are available and among them certain drugs may be used, although some of them are possessed of distinct danger. With these limitations in view the most serviceable drugs are alcohol, the preparations of bromine, of opium, chloral hydrate, amylene hydrate (dormiol), paraldehyde, hedonal, sulphonal, trional and hyoscine (scopolamine). Each of these drugs has its own indications, contraindications and dangers which as a rule are learned only after familiarity through use.

FRANK (Minsterlingen in Switzerland) read a communication on the relations between the ordinary court sentences and the mental condition of criminals. The meager knowledge of judges and lawmakers in the field of diseases of the mind and nervous system is really a menace, in his opinion, to the interests of mankind. To put the question otherwise, for example, the Court has little reference to the mental condition of the offender in passing sentence; the mental and nervous health of the prisoner demands some attention. Relief may come from the side of psychiatrists who may by degrees correct this ignorance in the minds of the jurists. In the first place some of the methods of cross-examination followed in courts demand criticism. The dictum which is usually followed in Germany that, before sentence is passed on a certain class of criminals, examination must be made of their mental capacity, is unfortunately not followed in all commonwealths. Frank claims that the court doctors are not as a rule capable of deciding these questions properly. The examination of such patients as a rule demands methods which are natural gifts or personal acquisitions. Through proper examination it may even be established what the motive of the crime probably was. Moreover, it may be established, with due care and attention, how the criminal came to break laws, what was his mental attitude in the matter and under what external influences he labored. After sentence the criminal simply works out his time and is silent. There is no trace of an effort to treat each individual as such. After his sentence is ended no one is interested in his well-being; he departs and begins life anew. The legal formalities are again gone through with perhaps thirty or forty times or oftener in the name of the sovereign and law and also according to precedent. A fundamental psychiatric knowledge on the part of the jurists would be a new field of labor which might be called criminal sociology or criminal biology. Such would probably be interesting and fruitful. Without this knowledge the State is not in a position to protect in the fullest sense of the word the life, health and property of each person. Frank, therefore, demands a practical course in psychiatry for lawyers and lawmakers. Moreover, at the time of examination due attention must be paid to the number and quality of the psychiatrists.

ALZHEIMER (Frankfort-on-the-Main) said that Lissaur has distinguished a typical and an atypical form of paralysis in one of his works recently edited. What he calls his typical form of paralysis embraces perhaps 80 per cent. of all paralyzed individuals. It is clinically distinguished by slowly, steadily progressive, distinct weakening of the muscles. The process of degeneration is generally limited to the frontal lobes of the cerebrum. What Lissaur has called atypical paralysis leaves the degeneration of the frontal portions of the cerebrum comparatively absent, but, on the other hand, shows a more or less localized wasting of the hinder parts of the cerebrum. Clinically the atypical paralysis has an interrupted course. Frequently there are seizures which point to disease in the cortex of the brain. Dementia appears in fixed degree as a late development.

It is partial, combined through other defects and more like the dementia of general disease of the brain. Examination with the microscope leaves no doubt that the change in the tissue of the brain of a paralytic is more or less syphilitic in character. Sometimes with one stroke of paralysis large areas of nervous tissue may be suddenly thrown out of use and then death is apt to follow soon. In the typical paralysis both hemispheres of the brain are as a rule equally diseased. In the atypical form, however, the atrophy is of high degree on only one side of the brain. For this reason there is commonly a wide difference between the condition of the two hemispheres of the cerebrum in the dementia of old age. There is sometimes a typical paralysis of Lissaur, while the dementia itself may be unusual in character. Under this heading belong the senile aphasias. Inasmuch as there is not only one, but many atypical forms of paralysis, it is better not to consider Lissaur's form as atypical paralysis in general, but as a special kind which may be named after him. A third form might be called foudroyant. Clinically it is distinguished by an acute active delirium with extraordinary seizures and excitement and sometimes convulsions which may appear as spontaneous, but which probably are choreic. In these subjects the whole brain shows widespread acute changes. A fourth form is confined chiefly to the cerebellum. According to later researches (Naecke) the cerebellum is regularly affected in one kind of paralysis in a low or high degree, usually atrophic in character. Therefore, the first symptoms in this disease are ataxia and vertigo pointing to the cerebellum. There are also very rare forms which are referable to the optic tracts. Just what share the tracts take and what part of the tracts is affected in this paralysis further study will probably reveal. There are other unusual forms of paralysis which are probably referable to tabes. Perhaps it may be that in its course a tabes may bring about some definite localized paralyzing degeneration. As yet, however, nothing definite has been effected in this connection. However, there are occasional peculiar hallucinations and illusions in tabes which would point toward the localization of the paralyzing degeneration in the deeper elements of the brain in contradistinction to the superficial elements which are usually affected in the typical paralysis. Finally, there are the paralyses of old age, occurring after the sixtieth year, which according to histological examination are not so very rare, but yet for the most part belong to the unusual forms. Clinically they show a senile dementia. The bodily accompaniments are of comparative insignificance.

Menzer, at the Gesellschaft der Charité-Aerzte in Berlin, November 28, 1901, read a paper on the relation between angina, rheumatism of the joints and erythema nodosum. The author has found diplococci and short streptococci in tonsils removed from cases of angina with rheumatism of the joints and at the same time he has discovered the same germs in the tissue about the tonsils also. He therefore regards these points as the entrance for these germs into the blood-current. In nodes cut out of the skin during erythema he found staphylococci. He also points out that in many cases of pneumonia the disease in the lungs is probably caused by infection not through the air-passages, but through the blood-current, probably from the large number of germs in the pharynx. In scarlet fever and measles he says the cause is usually the germs which are so common in angina and bronchitis and that these diseases are only a peculiar reaction to a very common form of infection.

Perthes, at the Medical Society of Leipzig, November 25, 1901, read a paper on his observations in Pekin while on duty there with the German troops. The arrangement of the average Chinese house is very suitable for the climate in having far projecting roofs to protect from the sun and a closed wall toward the north, made for the most part of paper, to keep out the sand storms. They have on the whole a good drainage system to take care of the water which falls in the rainy season and at other times. Most of these Chinese houses could be converted into hospitals with little difficulty. It was necessary to exercise great care with regard to water against the dangers of infection with typhoid fever and dysentery. The Chinese stoves, which gave out large quantities of carbonic acid gas, were another difficulty. By boiling the water, for which these stoves were very useful, these dangers were avoided. Sterilizing for operations was also quite easy. As to the actual medical and surgical conditions seen, the author gave the following: He operated on three cases of abscess of the liver, one after dysentery, one after typhoid fever and one tropical in origin. Only one of these died. He found the Chinese skilful and sensible in their aid to the surgeons and in their care of the sick. Such had been trained in the London Mission Polyclinic. The Chinese as a rule submit willingly to operation by foreign doctors. He also reported a number of cases, with photographs obtained with the epidiascope; one was a case of high-grade coloboma of all four extremities; another a fibroma molluscum affecting the left hand chiefly, with an abnormal development of the bone caused by the Chinese method of whipping; a case of stenosis of the urethra in a eunuch; gunshot fractures of the humerus, of the ulna and of the tibia, gunshot wounds of the ulnar nerve, and of the external iliac artery with secondary gangrene of the foot. Finally, he showed X-ray pictures of the feet of the Chinese women which show distinctly the changes in the outer form of the bones with a transformation of the whole bony anatomy of the foot.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninety-Sixth Annual Meeting, Held at Albany, January 28, 29 and 30, 1902.

Second Day—January 29th.

[Concluded from page 231.]

New Symptom of Short Umbilical Cord.—Dr. Samuel M. Brickner of New York detailed two cases of labor in which there was dystocia because of the presence of a very short cord in one case and of a cord of normal length in the other but wrapped twice around the child's neck. In the first case the patient complained of considerable pain and discomfort and immediately on the cessation of the pain it was noticed that the head was promptly retracted. The promptness of the retraction made it almost certain that there was a short cord in the case. Moreover, as the result of the head being drawn up from its position in the pelvis between pains there was intermittent urination that began each time just after the pain ceased. It is evident that this urination which is not voluntary is due to the fact that, the pressure on the urethra being relieved suddenly, there is a tendency for the bladder to evacuate itself as the result of the pressure of the head farther up in the genital tract on the bladder and soft tissues near it. Between pains it was also noticed that small amounts of blood were passed. When the baby was born it was found that the cord was barely ten inches and a half in length. Toward the end of the second stage of labor, when the pains were more frequent, there was no tendency to involuntary urination.

The reason for this seemed to be that there was no time for urine to collect between the pains.

In Dr. Brickner's second case the cord was shortened by being coiled around the neck of the child. It was twenty-two inches in length, but the coiling shortened it so much as to make it barely long enough to permit the birth of the child. The coils of cord were wound so tightly around the neck that when the head was born it was found impossible to release them and the cord had to be clamped with two artery forceps and cut between them. In this second case the intermittent bleeding was especially noticeable and was due to the fact that the placenta was slightly separated because of the pull upon it by the shortened cord. The definition of a short cord is not easy to give, because it is a relative matter. The length of cord necessary to allow easy birth varies in different women and with different placental insertions. The symptoms of the condition are the sharp recession of the head on the cessation of the pain, which usually attracts the obstetrician's attention at once. Other symptoms are pain at the placental site and a desire of the patient to sit up because she feels the need of the help of gravity for the birth of the child.

Treatment.—Very little can be done to remedy the condition without endangering the life of the child. If the cord is very short it is liable to be pulled out either at its umbilical or placental insertion. Instrumental interference in labor is apt to precipitate catastrophe. Expectant treatment is advised by all the authorities and seems to be justifiable under the circumstances.

Symposium on Diseases of the Pancreas.

Physiology of the Pancreas.—Professor R. H. Chittenden of Yale University, New Haven, said that knowledge of the physiology of the pancreas practically developed entirely during the last century. All practical knowledge has come since Claude Bernard's time. Wirsung discovered the duct of the pancreas, but did not realize the significance of the gland for digestion. Before this time the parotid and submaxillary glands, as well as the pancreas, were considered to be ductless glands. Von Graf and Sylvius studied the pancreas more closely and realized its digestive function. Peyer, after whom Peyer's patches are named, thought that the glands which he described as occurring lower down in the intestine were meant to supply by their secretion the substances furnished by the pancreas higher up. Brunner, whose name is associated with a set of glands of the intestines, studied the pancreas with assiduity. He removed all of the organ that he could reach from animals and noted the result. He confessed that portions of the gland were so deep that he was not sure of having removed all of it and rather concluded that a portion of it was left. Dogs thus experimented upon by him lived. He concluded therefore that the pancreas was not so important as had been suggested. It is extremely surprising to realize that two centuries went by before Brunner's experiments were repeated. Instead of devoting itself to observation and experiment, the medical world in the meantime occupied itself with elaborating theories Brunner noticed that dogs from which he removed the pancreas suffered from polyuria. It is probable that this was accompanied also by glycosuria, though of course Brunner was not in a position to recognize this fact. It was not until Minkowsky and Von Mering extirpated the pancreas completely in animals and obtained glycosuria that the second important function of the pancreas, namely, its internal secretion, was recognized.

Pancreatic Investigations.—Very little progress was made in the knowledge of digestion for a long while after Brunner's day. Spalanzani, at the end of the eighteenth century, and Beaumont, in America, at the beginning of the nineteenth century, accomplished more than any others. It was not until 1850, however, when Claude Bernard began his investigations, that the function of the pancreas in digestion was fully realized. Bernard showed that the presence of acid material in the duodenum gave rise to a flow of pancreatic fluid. Later it was shown that the presence of alkalies in the duodenum did not produce the same effect. Pavlow showed in recent years that the pancreatic secretion is dependent on the circulation and on nervous influences. The pancreatic fluid is strongly alkaline. It contains a starch-splitting enzyme, a fat-digesting ferment and a proteolytic ferment. Notwithstanding these important functions of the pancreatic juice, the most important feature of the gland is not its value as a digestive organ, but its importance as a provider of an internal secretion. It is this property that Von Mering and Minkowsky discovered. When the pancreas is completely removed from dogs, diabetes sets in in from four to six hours. This does not stop when the animals are fed only on proteids. The animal organism is evidently able to change proteid material into glucose which is promptly excreted in the urine. The glycosuria does not stop even when the animal is fasting.

Experimental Diabetes.—The state induced in these animals is true diabetes. Some time after the operation acetone, oxybutyric acid and other acids characteristic of diabetes develop in the blood. These continue to be present in the circulation until the death of the animal. Death usually takes place in one week and the animal rarely lives beyond four weeks. The most characteristic lesion found after death is fatty degeneration of the liver. Forty per cent. of the liver tissue is found to consist of fat material.

The diabetes does not occur in animals from which the pancreas is removed if a small portion of the gland is allowed to remain. Not more than one-fifth of the pancreas need be left to save the animal from diabetes. If paraffin be injected into the duct of Wirsung, diabetes does not ensue. The presence of the paraffin may cause an atrophy of the pancreas, yet sufficient of the pancreatic tissue is left to provide the internal secretion that prevents the nutritional disturbance that causes glycosuria. It has been found that if a small portion of the pancreas be grafted in some other part of the animal tissue before the gland is removed entirely, complete extirpation of the gland within the abdomen may take place without the production of diabetes.

Special Cells of Internal Function.—Some time ago Langerhans of Berlin described certain portions of the pancreas in which the cells are very different from the rest of the cells of the gland and which have no connection with the ducts of the organ. These cells are arranged in groups that are spoken of now as the islands of Langerhans. They resemble the structure of ductless glands. They are arranged with special reference, as Opie of Johns Hopkins has shown recently, to the blood-vessels of the glands. They are very closely in relation with a rich vascular supply that recalls the glomeruli in the kidney. It is evident that these cells supply the internal secretion of the gland. When diabetes occurs as a result of the removal or of a serious lesion of the pancreas, there is an excess of sugar in the blood. This is not true in the diabetes produced by the drug phloridzin. Nor is it true in the diabetes that results from puncture of the floor of the fourth ventricle. It is evident that the removal of the pancreas does not destroy the glycolitic function. The injection of the blood of an animal suffering from diabetes into another animal does not produce diabetes.

The feeding of diabetics with pancreatic gland substance does not check the diabetes. In this the condition differs very seriously from that which results after thyroidectomy, if thyroid feeding be kept up.

Pancreatitis.—Professor Flexner has recently found that pancreatitis may be produced by the injection into the ducts of the pancreas of artificial gastric juice. It has often been stated that acute pancreatitis may be due to the regurgitation of acid substances from the duodenum into the gland. In Flexner's cases, glycosuria occurred as the result of the inflammatory process set up. It would seem that these observations and the results of these experiments can be of important practical service to the clinician in understanding the relation of pancreatic disease to metabolism and of the pathology of the pancreas to the digestive tract.

Lower Blood-Pressure and Diabetes.—Dr. Chittenden said that the injection of proteids into the circulation is not infrequently acompanied by glycosuria. The most prominent effect of the injection of proteids is the production of lower blood-pressure. It would seem that this is somehow at the basis of the set of changes that lead to diabetes. A very interesting observation has been made recently in Germany and confirmed in this country by which it is found that injections of suprarenal extract cause glycosuria. The main influence of the suprarenal secretion is upon blood-pressure. It seems not improbable therefore that the glycosuric effect is exerted through the blood-pressure changes that ensue.

Diagnosis of Pancreatic Disease.—Dr. W. S. Thayer of Johns Hopkins University, Baltimore, said that the diagnosis of pancreatic disease is not encouraging. Pancreatic affections are discovered as a rule only when advanced and when already fatal changes have taken place. The pancreas is one of the most important of the digestive organs and yet serious changes may take place in it without producing any characteristic results. The organ is so deep and so covered by the stomach and bowels that it is practically out of reach of abdominal palpation. It cannot be palpated in the abdomen of ordinary individuals. In very thin people it can be felt when separation of the recti muscles exists. The pus of pancreatic disease very soon passes from the organ itself into the omentum surrounding it and causes an abscess of the omental bursa. This gives rise to a distinct tumor. It is felt as a deep immobile mass, not influenced by respiration. Its position in the abdominal cavity can be absolutely determined by inflating the stomach and large intestine with gas, when, of course, the tumor will be seen to be behind these organs. About one-half of all the cases of diabetes that come to autopsy have distinct changes in the pancreas. Opie of John Hopkins has recently shown that certain parts of the pancreas, the islands of Langerhans, are always in a state of hyalin degeneration when the patient has suffered from diabetes. So far in not a single case has diabetes existed without changes in this part of the pancreas. Nor has there been a pathological lesion of these structures without diabetes.

The Stools in Pancreatic Diagnosis.—As the pancreas is an extremely important digestive gland, it might be thought that advanced disease of this organ might be readily recognized by changes in the stools. As a matter of fact, however, considerable change may take place in the pancreas without its being noticeable in the stools. There are a number of other digestive functions that compensate for the pancreas. Certain ingredients in the stools are suspicious, however. The presence of more fat or of more soap than usual and of less fatty acids indicates that the fat-splitting ferment of the pancreas is absent from the digestive tract. The presence of too many undigested muscle fibers is also a suspicious sign. The trypsin of the pancreas is one of the most important meat-digesting ferments.

Acute Hemorrhagic Pancreatitis.—For the diagnosis of this condition there is little to be aded to Fitz's classical monograph on the subject. The affection usually occurs in adult or middle life in rather stout people and usually in patients with a history of alcoholism. The diagnosis of the condition should, however, be something more than a good guess. The most important symptom is acute pain in the median line in the epigastric region, usually with a tendency to extend somewhat toward the left. Considerable pain is felt when pressure is made over the lower ribs on the left side. The pain is caused by the pressure of the fingers being communicated to the pancreas through the spleen. This pain is frequently of an intense character that resists morphine, and chloroform may be necessary to give the patient comfort. The pulse is fast, the temperature not high. There is apt to be striking cyanosis with intense prostration and collapse. The patient usually dies in from three to four days. The conditions that come up for differential diagnosis are especially biliary colic, intestinal obstruction and perforation of the intestines. The pain very much resembles that of biliary colic, but is as a rule much more intense. In biliary colic, the pain is referred more to the right side of the epigastrium and has more of a tendency to be referred upward. Intestinal obstruction is simulated by pancreatic pain, but in the latter condition there is stercoraceous vomiting; no peristaltic movements are visible through the abdominal wall, no inflated coils of intestines are to be seen, and the localization of the pain is apt to be higher up. The differential diagnosis of perforation of the intestines is not easy except that there is much less collapse and the condition less rapidly reaches its acme. Mesenteric infarction gives a set of symptoms that resemble not a little acute pancreatitis. However, the symptoms, as a rule, are less violent.

New Urinary Symptom.—In a recent case of pancreatitis at Johns Hopkins Hospital, Opie found a fat-splitting ferment in the urine obtained from the dead body at autopsy. So far there has been no opportunity to confirm this observation in other cases and scarcely enough urine was obtained to make assurance absolute. No fat-splitting ferment has been found in the urine of other subjects examined for the purpose, however, and it seemed not improbable that this may give a new and valuable diagnostic sign for the recognition of acute pancreatic conditions.

Chronic Interstitial Pancreatitis.—The indurative inflammation of this form of pancreatic disease is thought to be due to an ascending affection from the intestinal tract. Vomiting is supposed to be the occasion for the regurgitation of some of the contents of the duodenum through the papilla and the duct to the pancreas. In this case the inflammatory process spares the cells of the islands of Langerhans, which are not directly in connection with the duct system of the pancreas. Diabetes does not always occur in these cases, and the reason is probably this sparing of the Langerhans areas. A certain association between cirrhosis of the liver and diabetes has been noted in a considerable number of cases. When it occurs it is the physician's duty to suspect the presence of interstitial pancreatitis. Chronic inflammatory condition of the pancreas is due to the same causes as the hepatic cirrhosis. The presence of a stone blocking the duct of the pancreas may cause a chronic inflammatory condition that finally leads to atrophy of the gland. This does not at any period, however, give rise to acute pain and it is probably impossible to recognize the presence of stone *intra vitam*.

Pancreatic Cysts.—Large cysts can be recognized by palpation. They may occur as the result of injuries. Some of them may be very large. One reported cyst filled the greater part of the abdomen. Retention cysts of the pancreas are usually small and as a rule cannot be recognized on palpation. Secondary carcinomata of the pancreas are not readily recognizable. Large tumors are not the rule, and it is only their induration that sometimes makes it possible to feel them through the abdominal walls.

Surgery of Pancreas.—Dr. Roswell Park of Buffalo described the methods and technic of operations upon the pancreas. He said that recent experience has shown that it is perfectly possible to reach the pancreas for surgical intervention without seriously endangering the patient's life, and that it is possible to remove portions of the gland and to open cysts without submitting the patient to unjustifiable risk. The advance in the surgery of the pancreas represents some of the best work that has been done in surgical science during the last decade. Notwithstanding the way in which the pancreas is bound down by firm tissue supports, the organ sometimes becomes loose and may be quite movable. Prolapse occurs and sometimes makes the organ quite easy of palpation from the abdominal wall. Functional disorders of digestion result from prolapse of the pancreas, partly because of the interference with pancreatic function and also because of mechanical interference with other organs and because of the influence of nervous reflexes upon important intra-abdominal functions. Dr. Park said that malignant tumors of the pancreas are practically without hope. Excision of the splenic end of the pancreas is not only justifiable, but perfectly possible. The splenic artery runs along the upper border of the pancreas and may be wounded during operations upon the gland. This artery was tied once by Mikulicz without serious result, and both the splenic artery and vein have been tied without necrosis resulting. The removal of portions of the pancreas is perfectly feasible. In six out of nine cases in which this was attempted the result was success. The old practice of opening the cyst of the pancreas and fastening the cyst-wall to the edges of the abdominal wound may still be followed with hopes of good results. The secretion may continue for a long time, but eventually the condition will improve. In a recent experience a copious secretion of pancreatic fluid for months issued from a cyst and Dr. Park almost despaired that his patient would ever be dry again. After a time however complete and very satisfactory recovery took place.

Acute Pancreatitis.—This affection presents differing clinical features according to associated complications. Fat necrosis or suppuration, or hemorrhage may occur; each of these conditions gives special indications. The symptoms frequently point to some severe condition of the abdominal organs that may be intestinal perforation, or acute intestinal obstruction, or pancreatitis. An exploratory incision must be made to render the diagnosis absolute. Wherever pus-formation has taken place the indication, of course, is for its evacuation. The abscess should be thoroughly opened and the lesser cavity of the peritoneum packed with gauze. Any delay in the evacuation of purulent collections in the pancreas is almost sure to lead to a fatal issue. The outlook in these cases, however, is not very encouraging, even under the most favorable circumstances.

Hemorrhagic Pancreatitis.—There is some mysterious connection between the pancreas and tendencies to hemorrhage. Anders collected forty-six cases of hemorrhagic pancreatitis. The more acute the symptoms of any form of pancreatitis the greater the danger. If pus formation does not follow hemorrhage, there is not very serious danger. Pus, of course, must be removed and posterior drainage instituted. Necrotic portions of the pancreas must be removed as far as possible and drainage instituted in order to help the tissues in the disposal of necrotic material. It is perfectly possible to drain the pancreatic space from behind. Even the subphrenic space can be drained through an incision between the tenth and eleventh ribs in the axillary line, as has been shown by a recent experience of Lund. In a late case of Mayo fat necrosis took place, although the patient was thought to be suffering from gangrenous cholecystitis and the drainage was provided on the right side. The surgeon should intervene as early as possible when pancreatic symptoms are present. Dr. Park has established as a rule of action in these cases for himself the same rule he follows with regard to appendicitis and fracture of the skull, namely, *when in doubt operate early.* When delay is possible there will usually be no need of operation at all. When symptoms are at all serious, however, delay is almost sure to be regretted and the surgeon has lost an opportunity to save life.

Pancreatic Pathology.—Dr. George Blumer of Albany said that the most important discovery in pancreatic pathology made in recent years was that by Opie of the connection between the lesions of the islands of Langerhans and diabetes. These islands of pancreatic cells have in connection with them a vascular arrangement which resembles somewhat that of the glomerulus of the kidney. So long as these portions of pancreatic tissue remain unchanged diabetes does not occur. If only one-fourth or one-fifth of the pancreatic glands remain no diabetes occurs in experiments upon animals. This is not due to any effect upon the nervous system in this part of the body, because the warding-off of diabetes may be secured also by the transplantation of the glands. It is evident that some internal secretion of the pancreas prevents diabetes. One serious objection to a theory connecting the pancreas with diabetes has been the fact that fatal diabetes sometimes runs its course apparently without changes in the pancreas. It is possible, however, that serious changes in the islands of Langerhans might be missed, for they occupy only a small portion of the gland. Some years ago Hansemann of Berlin showed that, even in cases in which the pancreas was seemingly completely destroyed by tumor formation, some typical pancreatic tissue remained. These portions might well supply the internal secretion necessary to prevent diabetes. In cases in which pancreatic tumors practically completely replace the gland itself, Hansemann suggested that the tumor cells, though not in themselves true pancreatic cells, are the descendants of pancreatic cells and might well furnish a similar internal secretion. This explanation seemed far-fetched to some pathologists. It is well known, however, that metastatic liver tumors are frequently found to contain biliary secretion and salts of biliverdin have been demonstrated to exist in them.

Acute Pancreatitis.—This may be produced by a number of micro-organisms and experimentally has been set up by injections of diphtheria bacilli, the bacilli coli communis and the bacillus pyocyaneous. It is not impossible that these micro-organisms find their way into the pancreas from the intestine. There are various forms of antiperistaltic movements in the intestine that may favor this regurgitation into the pancreatic duct. Hlava, the pathologist at the Czechish University, at Prague, showed that by injecting artificial gastric juice into the pancreatic duct, in imitation of what he considered might occur dur-

ing vomiting, pancreatitis was set up. Blumer himself has seen a case in which a stone lodged in the ampulla of Vater, the common opening of the biliary and pancreatic ducts into the intestine, prevented the outflow of fluid and yet did not completely close up the connection between the biliary and pancreatic passages. In this case the pancreatic duct was found bile-stained, showing that, as might be expected, bile had flowed over into the pancreas. Bile is secreted under greater pressure than is the pancreatic fluid, so that this is the natural consequence of such a condition.

Biliary Etiology of Pancreatitis.—It is easy to understand how hemorrhagic pancreatitis might occur as a consequence of the irritating presence of bile in the pancreas. In the majority of cases of acute pancreatitis there is a history of gall-stones. In a number of cases a stone has been found in the common ampulla of the duct. Hlava's experiments have been confirmed by Flexner's observations.

Hemorrhage or Inflammation.—A question which always arises in these cases of hemorrhagic pancreatitis, Was the hemorrhage the first symptom or did inflammation precede the hemorrhage? Flexner's observations seem to show that the hemorrhage and inflammatory condition are simultaneous. The presence of blood alone would not give rise to inflammation. This has been shown experimentally on animals by the injection of sterilized blood. Inflammation alone would not give rise to hemorrhage, without some additional cause. The chronic induration which occurs comparatively frequently in the pancreas is due to the presence of small amounts of bile repeatedly finding their way into the pancreatic duct. In operations for biliary colic it is not an unusual thing for the operator to find that the head of the pancreas is quite hard. This has led sometimes even to the suspicion of malignant disease of the pancreas. It is only a condition, however, of chronic indurative pancreatitis.

Pancreatitic Fat Necrosis.—The fat necrosis that occurs so frequently in connection with pancreatitis is due to the steapsin finding its way over the tissues. This has been confirmed by Flexner and by Opie. The mechanism of distribution of this fat-splitting ferment is hard to understand. How it finds its way to distant tissues is the next question that must be cleared up in order to make the process of fat necrosis clear.

Surgery of Acute Pancreatitis.—Dr. Joseph C. Bloodgood of Johns Hopkins, Baltimore, said that acute pancreatitis presents two distinct features. The first is to be seen only during the early hours, or perhaps during the first day or two of the disease. The second is the suppurative condition that results from the acute inflammatory process or from the peripancreatic abscess which forms as a result of the virulent infection. Before suppuration sets in, surgery can accomplish nothing and interference is contraindicated. As soon, however, as suppuration takes place, the pus should be evacuated. All hope of success in these cases depends on the early recognition and the early incision of the abscess.

Expectant Treatment.—There are about eleven cases in recent literature in which recovery from acute hemorrhagic pancreatitis took place without any operation. In two of these cases not long after recovery from the disease, death took place from an entirely different cause and the distinct signs of a healed hemorrhagic pancreatitis were found at the autopsy. One patient was aspirated by Brentano, who withdrew bloody serum, thus apparently proving the diagnosis correct. One of the cases was reported by Jacobs and occurred in a child who had just recovered from an attack of mumps. This is a doubtful case. In one very singular case most of the pancreas sloughed away and was passed through the bowel.

Deaths from Pancreatitis.—While there are a certain number of recoveries from pancreatitis there are a number of reported fatalities. Twenty-one patients died without operation. Three of these reached their fatal termination within twelve hours. One of the patients survived as long as the seventh day. As a rule operation in these cases only serves to confirm the diagnosis and is of no benefit to the patient. Nineteen cases operated upon died. Many of them died on the operating-table. Practically all of the patients died from collapse, most of them within forty-eight hours. For non-purulent pancreatitis the expectant treatment is better than operative interference.

Purulent Pancreatitis.—As soon as pus forms it must be removed. In some thirty cases of purulent pancreatitis operated upon there are nine reported recoveries. Eleven patients treated expectantly died without a single exception. As a rule in the operative cases operation had been delayed too long. If done at any early stage surgery will save lives.

Gall-stones in Pancreatitis.—The diagnosis of pancreatitis must always remain a little doubtful. There are certain features, however, that encourage operation early in the case and without waiting for absolutely definite symptoms. If the symptoms of acute pancreatitis develop in a patient who has suffered from gall-stone an exploratory incision should be made early, for the diagnosis of pancreatitis is almost surely correct.

Traumatisms of Pregnancy.—Dr. Denslow Lewis of Chicago said that as the result of a very interesting case in his own practice, nearly fifteen years ago, he had collected from literature a series of cases of the injuries that had been inflicted upon women during the course of pregnancy. His own case occurred in the wife of a physician. Her husband was endeavoring to perform an abortion on her at the third month of her pregnancy, using a male silver catheter to rupture the membrane and loosen the fetal attachments to the uterus, when the silver catheter disappeared. Dr. Lewis was consulted some twenty-two hours after the event, and made an abdominal incision, but had great difficulty in locating the catheter. Practically all of the woman's intestines had to be removed from her abdomen before the catheter was found, up under the liver. It was removed and the abdominal incision closed. The pregnancy continued despite the surgical interference, and at the end of six months a healthy child was born and is still alive. In another case there was a history of the patient endeavoring to bring on abortion by the introduction of a glass rod into the uterus. It disappeared, but no abortion took place. About three weeks after abortion occurred, but the glass rod not having appeared the girl became alarmed. The rod was found near the left kidney and was removed without difficulty and without serious consequences. Dr. Lewis has found a laminaria tent in the peritoneal cavity that had found its way there as the result of attempts at dilatation of the uterus. Such foreign bodies may remain in the uterus for a long time without producing serious inconvenience. Dr. Lewis once removed a wooden stick five inches long and almost as thick as a lead pencil that had remained in the uterus for nearly two years after an abortion. A bougie six inches in length and the size of an ordinary male sound, that had been used for purposes of abortion, appeared through a fistula over the sacrum. It had ulcerated its way out through the thick tissues of this neighborhood without producing anything more than local symptoms. Hairpins and knitting needles are sometimes introduced to great depth through the abdominal wall with the idea of

bringing on abortion. In one case a young woman introduced a knitting-needle through her umbilicus for a distance of over five inches. She finally pushed it completely into the abdominal cavity. Pus came from the navel, but the knitting-needle made its exit through the vagina. In one case where a knitting-needle was used for the purpose of abortion, it failed to produce the desired emptying of the uterus but left a permanent pigmented spot on the child's buttocks. Dr. Lewis considers that any practitioner when called to see a case of abortion should suspect the possibility of its having been procured by some instrumental means and should looke for the foreign body. This method of dealing with these cases may prove life-saving. If the membranes are ruptured in an abortion, it is better to remove all the fetal products at once. The use of the curette under these circumstances, however, is dangerous. Every physician of any considerable experience has had opportunity to observe that the curette may easily pierce the uterine walls and enter the abdominal cavity.

Removal of Foreign Bodies.—As a rule a vaginal incision should be made if it is possible to remove the foreign body in this way. It by no means necessarily follows that such operative interference may produce abortion. It is wonderful how much disturbance the pregnant uterus will stand without emptying itself. A number of pregnant women have fallen down stairs and yet recovered completely without premature delivery. In one case a pregnant woman was caught between a wall and a heavily-loaded wagon. Her pelvis was crushed so that the internal diameter of the pelvis was less than two inches, but she recovered completely and carried her child to term. The outlook in these cases is not nearly so hopeless as might be anticipated.

Abdominal Wounds.—Insane women have on a number of occasions performed a Cæsarian operation on themselves, cutting open their abdomens and wombs and removing a living child. Many of these women have recovered without serious consequences. Dr. Harris of Philadelphia collected a series of cases absolutely authentic and well substantiated in which women had been eventrated during pregnancy and their wombs opened by the horns of cattle. The results of these injuries showed that the artificial removal of the child in this way gave less fatality than a Cæsarean operation in hospital practice before the days of antisepsis.

Tendon Transplantation.—Dr. Arthur W. Elting of Albany read a paper on the use of tendon transplantation in the treatment of paralytic deformities. He reviewed the history of this form of surgical interference in paralytic cases and showed how much benefit has been derived from it. Formerly paralytic deformities were considered absolutely hopeless as regards any possible benefits to be derived from surgery. The deformity was nervous in origin and was therefore considered beyond the domain of surgical interference. Now the condition of such patients can be so much improved that from being helplessly bedridden they become well able to help themselves and are even able to engage in reasonably laborious occupations. Dr. Elting spoke of the various methods that had been employed and commended especially the idea of splitting the tendon of healthy muscles in order to divide part of its insertion with paralyzed muscles. Some surgeons now attach the tendon of the muscle to be transplanted directly to the periosteum of the bone that is to be affected, thus securing with absolute certainty the movement to be expected. Dr. Goldthwaite of Boston introduced the method of quilting the tendons into one another in order to secure firm adherence. Dr. Elting has recently applied a modification of this method in four cases. In two of his patients both feet were affected by the paralysis. In the other two only one limb was affected. These patients have been transformed from helpless cripples into active members of the family and two of them consider themselves practically well.

Pronunciation of Hallucis.—Dr. R. H. M. Dawbarn of New York said that Dr. Felting was the only surgeon whom he had heard use the term who knew how to pronounce properly the word "hallucis." It is usually caled hal-lu-cis, the second syllable being made long. This word has a peculiar history. There is often mention of the word hallux in such expressions as hallux valgus. As a matter of fact, there is no such word in Latin as hallux. There is such a word as hallex and its definition is pollex pedis, that is the thumb of the foot. Since one is using scientific terms, supposedly of Latin origin, it is only proper Dr. Dawbarn thinks to use them with due regard to their true signification.

Pneumogalactocele of the Breast.—Dr. J. Milton Mabbot of New York described a case in which the patient suffered from a tumor of the breast that developed after an abscess. It was thought that milk alone would be found in it, because there were no general inflammatory symptoms. Percussion over the tumor, rather to the surprise of the surgeons, gave a tympanitic note that showed the presence of gas. Dr. Mabbot prefers the term pneumogalactocele mastitis aerogenes for these cases, because there is no inflammation present, and milk, not pus, is found. The etiology of the tumor was somewhat in doubt. The fluid removed was found to contain large, somewhat broken-down cells resembling colustrum corpuscles and evidently of milky origin. From the fluid a micro-organism was isolated that belongs to some hitherto unidentified class. This micro-organism grows in long thin filaments arranged in long chains. Some time before the development of the tumor normal salt solution had been injected under the breast because of loss of blood during labor. It was thought that perhaps air might have found its way into the substance of the breast during this process.

Micro-Organism and Gas.—It is possible that the gas collected in the case may have been due to the presence of this micro-organism, which was actively motile and grew well on most of the ordinary culture media. The fluid was not examined for anaerobic micro-organisms and the possibility must almost remain that it was a microbe belonging to this class that caused the gas formation. The gas in the tumor was collected over water in a test-tube and was sent to the laboratory to be examined, but proved not to be sufficient in amount to enable its character to be recognized with absolute certainty. A curious observation as the result of the existence of air and liquid together in the cavity of the tumor was the occurrence of distinct succussion sounds, splashes and bubbles, at a distance of several feet from the patient when the tumor was shaken.

Simple Home Modification of Milk.—Dr. Rowland G. Freeman of New York said that the important feature of the artificial feeding of children is the imitation of mother's milk and the preparation of food bearing some definite relation to the needs of the growing organism. Such food need not be prepared with absolute, but with approximate correctness. Dr. Freeman suggests a method by which milk modification can be carried on at home without undue complexity of directions. Gravity cream on an average contains four parts of fat to one of proteids. If mixed with an equal quantity of milk the proportion is about two to one. As a rule the difficult part of the problem of preparing infant food is to obtain the proper proportion of proteids and fat. If these are once obtained sugar may be added. As gravity cream contains about four parts of fat to one of proteids, this can well form the basis of all milk modi-

fications. Simple dilution with milk will give the varying proportions of fat and proteid and the addition of sugar obtained for the purposes in proper weighed amounts is easily effected. As a rule the number of feedings in the day should be decided on and then the quantity of food necessary for the day prepared at once according to the method selected.

Third Day—January 30th.

Double Dacryo-Adenitis.—Dr. D. H. Wiesner of New York reported a case of double infection of the lacrimal glands—an extremely rare affection. The ailment causes no little discomfort. Hot applications are usually advised, but Dr. Wiesner found that ice-applications relieved the patient more rapidly and satisfactorily than the commonly recommended hot applications.

Treatment of Pneumonia.—Dr. Reynold W. Wilcox of New York read a paper on the treatment of pneumonia by the method suggested some time ago by French clinicians. The feature of this method of treatment consists in the effort to overcome the toxemia, which is usually the most serious element in a case of pneumonia. The toxic symptoms are best combated by means of large and increasing doses of creosote. The remedy must be pushed to tolerance. An important part of the intoxication in pneumonia that weakens the patient and renders the prognosis more unfavorable comes from the absorption of poisonous products from the intestinal canal. An important accessory feature of the treatment then is the administration of intestinal antiseptics and the maintenance of the intestinal canal as far as it may be possible in a state of asepticity.

Mortality from Pneumonia.—In addition to the existence of complications or organic lesions in important structures at the time the pneumonia developed, the most important etiological factor and mortality from pneumonia is undoubtedly the toxemia. The results obtained with direct antitoxic treatment have been most encouraging. Creosote especially has proved its value and there seems no doubt that the mortality in private practice under the use of this method of treatment should come down to three or four per cent. in the very near future.

Obesity of Adolescence.—Dr. Heinrich Stern of New York read a paper on those cases of obesity which develop during the third decade of life and signs of which are already present during the second half of the second decade. It is not infrequent to find that people put on weight about the close of their second decade of life. This is as a rule distinctly pathological and not physiological. It needs prompt treatment, and to allow it to continue is to prepare for serious discomfort before middle life and even a shortening of life. In children there is a distinct tendency to put on flesh, but this does not usually make itself very noticeable until between the ages of ten and twelve. As a rule, shortly before puberty, individuals become stouter than before. It is as if Nature were accumulating force to meet the drain that is about to come. The fat put on at this period corresponds somewhat to the obesity that occurs after castration or the menopause.

Adolescent Obesity.—There is a transitory obesity of adolescence just before the acme of physical development is reached. In this form the accumulation of fat tissue is apt to be more on the chest, on the breasts and on the extremities, than in ordinary obesity in which fat accumulates on the abdomen. This form of obesity is not always associated with the consumption of large amounts of food, but there may even be a certain amount of anorexia or a capricious appetite. Dr. Stern is inclined to place the etiology of this form of obesity and its accompanying symptoms in some disturbance of the thyroid or parathyroid glands.

Thyroid in Obesity.—Just about puberty the thymus gland disappears and a marked increase of the thyroid gland occurs. Girls have a more marked increase of the thyroid gland than boys. They also have a more distinct tendency to put on flesh. It would seem that the female organism needs more thyroid substance for proper metabolism than does the male organism. Any functional disturbance of the thyroid gland is noted more in women and leads to obese conditions. It is well known that thyroid medication has a distinct tendency to lessen obesity, especially in young people. This would seem to show that some absence of thyroid function is at the bottom of the tendency to obesity.

Accompanying Symptoms.—At times the tendency to obesity is accompanied by cardiac dyspnea and chlorosis. These occur only in extreme cases. For such patients Dr. Stern has found the following formula of great service:

℞ Ac. Arsenious .....gr. $^1/_{60}$
Adonid .....gr. $^1/_{12}$
Thyroid gland.....gr. ij
Sig.: One powder two or three times a day.

Broken Necks.—Dr. Reginald H. Sayre of New York said that in popular medicine a broken neck is usually considered to be inevitably fatal. Most of the cases actually die, but some of them can be saved. Dr. Sayre exhibited a series of photographs of patients who had suffered from broken neck and described the characteristics of different forms of the injury and the treatment proper for each class of cases. Many of the cases survive only to perish later from bed sores or bladder infection, sometimes due to instrumentation with dirty catheters. Such accidents must, of course, be sedulously guarded against.

Diagnosis of Cervical Fracture.—The diagnosis of fracture of the cervical vertebræ can be made from the position of the head and actual palpation of the position of the bones. In fracture of any of the three upper vertebræ, the head is twisted as in torticollis and is somewhat raised. Dr. Sayre contrasted the position with that of a case of inflammation of the second cervical vertebra in which the face is always held lower. The X-rays are of importance in the diagnosis of these conditions, but it is often extremely difficult to obtain satisfactory radiographs.

Treatment.—These cases need supporting treatment much longer than has been thought. Correction should be made slowly and gradually. Immediate correction may prove fatal. Dr. Sayre has devised a plaster-of-Paris helmet, which is put on at first in connection with a plaster-of-Paris jacket and then the helmet is cut loose from the jacket after some days and the head gradually straightened. It is impossible to keep fractures of the cervical vertebræ properly immobilized with sand-bags and other temporary apparatus; therefore some form of permanent apparatus must be employed. The prognosis of the cases is not nearly so bad as has been thought and several men with broken necks are exhibiting themselves in the museums throughout the country.

NEW YORK ACADEMY OF MEDICINE.

Section on Orthopedic Surgery.

Stated Meeting, Held December 20, 1901.

George R. Elliott, M.D., Chairman.

Rheumatoid Arthritis.—Dr. Royal Whitman presented a child, twenty-one months old, suffering from a condition which had at first been mistaken for and treated as tuberculous disease of the knee-joint. The

particular interest lay in the fact that it was rheumatoid arthritis; the mistake was not uncommon when the larger joints alone were affected, as the signs were similar in the early stage. At present, both knees are involved, also a wrist, ankle and the fingers. The case was presented because rheumatoid arthritis was rare in young children and to call attention to a common error in diagnosis.

Torticollis.—Dr. Whitman presented a patient showing the ordinary treatment of confirmed torticollis. The permanency of the cure was the especial point to be noted. The treatment was by the open method of complete division of all the contracted tissues, overcorrection of the deformity and fixation for several weeks in plaster of Paris. The advantage of a thorough operation was the ability to dispense with apparatus, while after the subcutaneous method apparatus was often necessary because it is not always possible to completely overcome all deformity. The case showed to a moderate degree hemiatrophy of the face, which was very marked in some instances.

Radical Treatment of Clubfoot.—Dr. Whitman also showed the result of radical treatment of clubfoot in a child eight years of age. One foot had been cured by the ordinary means in early life; the other foot was operated upon July last. The foot that recovered first was much larger than the other—an illustration of the effect of deformity in retarding development. He considered the Phelps open operation the best of the more radical operations for the ordinary clubfoot of childhood and adolescence, the advantage being that the inner border of the foot was lengthened instead of the outer side being shortened, as was the case in certain operations on the bones. This patient was not confined to bed for more than one week; after that it was allowed to walk about on the plaster-of-Paris bandage.

Dr. W. R. Townsend said, in referring to the case of torticollis operated upon by Dr. Whitman, that he could not agree with the latter as to the disappearance of the scar. He had seen many of these scars which looked well shortly after operation, but which had a tendency to grow more unsightly; he had even known keloid to develop. He thought that at all events patients should be warned of the possibility of a scar remaining.

Dr. Homer Girney stated that he had seen a number of cases treated by both methods, open and subcutaneous. He had seen several scars disappear in young children. He considered the subcutaneous method the safest except in very severe cases.

Dr. T. Halsted Myers said a transverse incision would give the same exposure of the operative field and would enable the deformity of the scar to be better concealed.

Dr. Whitman had had no experience with keloid developing late in the scars; if such appeared it was usually within a few months after operation, he thought. He stated it as his experience that the scars practically disappeared.

Extreme Deformity of Rickets.—Dr. V. P. Gibney presented two cases showing extreme deformity of rickets. The upper arms, back and legs were involved, in one case giving the typical deformity of the disease. The second patient showed the lateral spinal curvature, the typical deformity of the thorax, beaded ribs, also deformity of the legs and arms. Both were being treated in the Bradford frame made convex, in conjunction with general constitutional treatment.

Clubfoot Shoe.—Dr. Gibney also presented a patient wearing a clubfoot brace seen in Hartford and used by Dr. Cook as a modificaton of Taylor's clubfoot shoe. In private practice he had been able with this apparatus to control some of the most obstinate cases. In the case presented, treatment was begun when the patient was six weeks old. Several forms of apparatus had been used from time to time, but relapse had occurred. At present, after wearing the modified shoe, the child holds its foot in perfect position and walks without deformity. The apparatus is a good retentive one, though it does not take the place of operation.

Talipes Equino Varus.—A case of talipes equino varus, a child twenty-one months old, was also shown by Dr. Gibney. The deformity was extreme and was corrected under an anesthetic and various methods had been employed; the last time it was seen it presented the typical "reel foot." It was thought that if the head of the astragalus could be removed, the fascia divided and the foot replaced a cure could be effected. A relapse occurred after six to eight months. Under anesthesia the foot was forcibly put in calcaneovalgus. Later a clubfoot spring with pelvic band was put on and served fairly well, except that two sets of apparatus had to be kept on hand. Finally, the modified braces were used successfully.

Dr. Gibney also presented a boy, eleven years old, for diagnosis. He came to the hospital some months ago with the history of an injury four weeks previous, having fallen, striking his hip. He got up and limped about, but the next night could not sleep; he had fever with delirium. On admission to hospital he walked with thigh flexed on pelvis, had little fever and complained of pain in the hip extending to the knee. He was thought to have hip disease and was treated with pulley in bed. After three weeks, the angle of extension was 110 degrees, flexion normal, practically no pain on pressure. There was no apparent abscess and the spinal column was not involved. The diagnosis became doubtful. In October fluctuation was thought to be detected under the vastus externus. Incision was negative. The original diagnosis was finally abandoned and the case was considered one of periarthritis.

Dr. Myers asked Dr. Gibney what would be his prognosis in the case of the spinal curvature in the rickety patient.

Dr. Whitman stated in reference to the case of rickets, that when the patient entered the hospital the spinal deformity was thought to be the most serious of the distortions, and that for that reason the patient was placed on the frame.

Dr. Gibney said that Dr. Whitman had partly answered the question of prognosis. He thought the child should be kept in overextension for a while longer, and that after that a brace would keep the spine in place; as the child developed the deformity would be in a measure outgrown. He considered the cases easy to manage so long as they could be kept under observation in a hospital; outside, the prognosis was not so good; no manual force had been applied to these cases yet.

Dr. Judson said that the clubfoot shoe that was shown seemed more like a modified Taylor brace. It was evidently an effective apparatus. He noticed the absence of an ankle-joint, which was very properly omitted, as better leverage was thus obtained and there was no good reason for the fear that want of motion in the brace would impair ultimate motion in the ankle.

Incipient Hip Disease; Recovery.—Dr. A. B. Judson presented a girl, eight years old, who had been before the Section on November 16, 1900. At that time the history of left hip-disease, covering twelve weeks, had included inconstant lameness, knee pain and reflex, night cries, muscular atrophy and limitation of motion. A steel crutch and high shoe had been worn from November, 1900, to November, 1901. Recovery had been so complete that the only traces were ⅜ inch shortening and ¼ inch muscular atrophy. The case illustrated

the importance of early diagnosis. Traction and immobilization had not been sought. Recovery took place when the limb was freed from the weight of the body by being made pendant. In this artificial environment the focus, which otherwise would have broken into flame, was quenched.

Device for Deformities of the Knee.—Dr. Judson presented a girl, ten years old, wearing a device useful in deformities of the knee. The patient was Case III., white swelling of the knee, presented to the Section October 20, 1899. The problem was to prevent the fixative brace from seeking the inner side, where it caused knock-knee, and to keep it behind to oppose flexion. The brace was made of one piece with the shoe, in such a way that, when the shoe was on, the brace would be in the proper place. A light steel bar extended up the leg and was fastened to the upright part of the brace by a sliding ring keeper. Its lower part, bent at a right angle, was screwed to the under side of the heel of the shoe at an angle to secure the effect desired, keeping the brace behind to oppose flexion or to the outer side to oppose knock-knee.

Softening of the Tibia.—Dr. J. P. Fiske presented a case of localized softening of the tibia at the age of adolescence. The patient, a girl, now fourteen years of age, was first seen in 1898, when she complained of localized pain in the lower part of the leg well above the ankle-joint, thought to be a referred pain due to improper gait. A strap bound around the part brought no relief. The curve at the lower part of the tibia increased. At this time a positive diagnosis of tuberculous disease was made by a distinguished consultant and fixation advised; plaster splint was worn for six months. At the end of that time the leg was in the same condition except that atrophy had occurred; measurements showed that the tibial curve had increased. Two months later exploratory incision revealed negative results. In February, 1901, an osteotomy was performed in the lower quarter of the tibia, the fibula shortened one-eighth inch, the deformity corrected and the leg put in plaster. Ten days after the operation the patient was fitted with an ambulant splint and six weeks later walked without the apparatus. Since then there have been no symptoms. The diagnosis of softening of the lower part of the tibia seems to have been the proper one. There is no difference in the length of the tibiæ.

Congenital Deficiencies.—A second patient presented by Dr. Fiske was one of congenital absence of the fibulæ and outer side of foot, with equinus. The patient was seen at the age of one year. The fibulæ and several of the metatarsal bones were absent and the heel was undeveloped. An osteotomy was performed at once with tenotomy on the tendo-Achillis, and the position of the feet corrected. At present the child is able to go about with a light brace.

Double Congenital Clubfoot.—Dr. Leonard W. Ely presented a patient, one year old, showing the result of treatment for double congenital clubfoot. The point of interest was that the right foot was treated uninterruptedly with a brace and the left with plaster of Paris. In contradiction to the general idea that plaster of Paris causes atrophy, the right leg was shown to be much smaller than the left.

Tendon Transplantation.—Dr. R. A. Hibbs showed the result of tendon transplantation done in July, 1901, for paralysis of the tibialis anticus muscle. The extensor proprius hallucis was inserted into the periosteum of the scaphoid and its distal end into the first division of the common extensus. The patient, twenty-one years of age, exercised a good deal of intelligence in perfecting the action of the muscle with its new attachment. The foot had been in a position of marked valgus, with the scaphoid very prominent. The deformity was completely corrected. He stated that in all his cases during the past two years, when possible, he had attached the transplanted muscles to the periosteum.

Dr. Myers said the point mentioned by Dr. Hibbs, attaching the tendon to the periosteum, was important; he did not believe in matting tendons together; the connecting bands stretched and the union was ineffective. He had just dissected such a case. If the tendons were divided and the live one united to the tendon of the paralyzed muscle, often there was also stretching.

Dr. Whitman said that the operation of periosteal tendon transplantation had been extensively practised by Lange of Munich, who had reported many cases; his own experience with the operation had been favorable.

Dr. Fiske emphasized the importance of transplanting muscle tendons into the periosteum, especially when the muscle was to work at raising the inner side of the foot or the heel.

Congenital Dislocation of the Hip Under Treatment.—Dr. Elliott presented a child, aged two years, upon whom he had reduced a congenital dislocation of the hip by the Lorenz non-cutting method, showing the bandage in position. He presented the patient to show the position of the leg when the dislocation had been successfully reduced. A slight degree of hyperabduction was necessary with the knee pressed back slightly posterior to the transverse axis of the pelvis. There was frequently considerable difficulty in getting the head of the femur into the acetabulum and in getting the knee down to the mid transverse pelvic plane or posterior to it, but unless that could be accomplished the operation should be abandoned as a failure, as relapse was certain. In the case presented he felt quite positive of a good result.

BOOK REVIEWS.

Gynecological Pathology. A Manual of Microscopic Technique and Diagnosis in Gynecological Practice. For Students and Physicians. By Dr. Carl Abel, Berlin. Translated and Edited by Samuel Wyllis Bandler, M.D. With a Chapter on the Embryology of the Female Genitalia and the Pathological Growths Developing from Embryonal Structures. William Wood & Company, New York.

It is only reasonable that, with the development of specialties in medicine that concern the treatment of disease, we should find similar differentiation in such branches of the science as pathology. The present book is a most carefully written and valuable treatise on the subjects enumerated in the title and especially available for the gynecologist and the surgeon.

Part I. is devoted to technique, especially concerning the obtaining of material, the further treatment of it, the management of material obtained by laparotomy and autopsy and a list of instruments necessary for good work. Part II. deals with diagnosis and details the stages for the recognition of all conditions beginning with inflammation and ending with neoplasms. Such affections are discussed as they occur in the vulva, vagina, cervix, body of the uterus, tubes, ovaries and parovaria. Part III. is given up to the embryology of the sexual organs of the female. Special importance is given to pathological growths which develop from embryonal structures. Brevity and clearness mark the style. The text is rendered more comprehensible by one hundred admirable engravings, with numerous distinct explanatory notes for each.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 80. NEW YORK, SATURDAY, FEBRUARY 15, 1902. NO. 7.

ORIGINAL ARTICLES.

ADDRESS TO THE GRADUATES OF THE TRAINING SCHOOL FOR NURSES OF THE COLORED HOME AND HOSPITAL.

BY T. GAILLARD THOMAS, M.D., LL.D.,
OF NEW YORK.

WHEN I was requested to address you upon an occasion of such interest as this, which gives you authority in the name of your Alma Mater to go forth and practise one of the most useful and excellent callings of civilized life, I accepted the invitation without hesitation for two reasons. First, knowing that great and praiseworthy efforts were being made to increase, expand, and multiply the very insufficient hospital advantages which this city has heretofore extended to its colored citizens, I felt urged by a sense of duty to do what little lay in my power to aid in so noble and so good a work. Second, a peculiarly kind, friendly, I may almost say affectionate, feeling which I have during all my life entertained for the people of your race prompted me to come before you and to bid you Godspeed upon the admirable career which you have selected for your life-work.

The first twenty-one years of my life were passed in South Carolina in the days of slavery. These were spent in immediate contact with people of your race, whose forefathers had lived for three or four generations under the control of mine. It would be almost impossible after all the confusing and misleading literature of the last half-century to convey to your minds the pleasant relations, the entire confidence, the general feeling of friendliness, which in my boyhood existed between the whites and blacks, except in very rare and unfortunate cases. This experience of my past life taught me to appreciate the kindly, gentle, affectionate nature of the children of Ham, and this feeling of my boyhood has never departed from me. You will not wonder that it should not have done so, when I tell you that the good colored woman, who during the period of my infancy acted as my wet-nurse, departed this life only about ten years ago, full of years and respected by the entire community in which she lived.

All this pleasant sentiment was in later years so suddenly and so rudely shattered by the cruel barbarities of war, that there may be some in this hall to-night who feel inclined to doubt the reality of my representations; but I pledge myself that I have dealt in no exaggeration of absolute fact. Let the skeptical turn to the annals of the Revolutionary War, and they will find unquestionable and abundant evidence of the love of the colored man for the white, so full of true devotion as to make him faithful even unto death. Half a century gapes between those days of my youth and to-night, and still the kindly feeling for your race clings to my mind, as the scent of roses to a broken vase!

Knowing the true mental and moral attributes of the colored race, I feel sure that its members have just the traits which will fit them for the calling to which you to-night pledge your devotion; and in saying this I do not by any means confine myself to the female sex. When the experiment, which is being made by the Colored Home and Hospital in reference to women, is extended to the male sex I feel assured that, for the reasons which I have given, it will prove a brilliant success. It is curious to observe how the mental attributes of certain nationalities appear to fit them for special callings. The English excel in all that relates to seamanship and horsemanship; the French instruct the world in the important and subtle art of cooking. This natural adaptability is due to certain inborn qualities, which, being developed by education, give these races an easy ascendency. So my knowledge of your race assures me of a similar adaptability on its part for the profession of nursing, which, with the required training, will lead to excellent results. Far be it from me, however, to prompt you to depend upon any such supposed natural gift for your future success in life. On the contrary, I propose to impress upon you that the day when a nurse can rely for success upon smiling amiability, a wise way of announcing wordy platitudes, and a habit of reciting lengthy cases of wonderful recoveries, has passed away forever. To-day more simple, more rational, and more sensible tests are applied, and she, who in this line of life hopes to win fame, must rely upon real merit, and upon that alone. Captivating manners, a pleasing personality, and a fascinating presence may for a time deceive the patient and her family, but the judicial doctor will never be misled by these, and will surely detect and expose the counterfeit.

This generous and noble community of New York—to my mind, the most attractive known to the world—is "long suffering and of great kindness." The result is that it allows great evils to live, increase, and grow strong without interference for long periods of time. Then it has the habit of crushing them with the sudden power of an enraged giant; even as it has recently done with the corrupt organization which has so long oppressed us politically. So it was when twenty-nine years ago a mere handful of noble, enterprising women overturned the miserable system of nursing, then extant, and laid the physicians and community of New York under a heavy debt of gratitude by establishing in its stead the system of trained nurses, into whose ranks you have the honor of entering to-night. As if by the

wand of an enchanter, old things in nursing passed away and all things became new. In the place of old and incompetent women, they gave us young and vigorous ones; for ignorance, they substituted intelligence and brightness; for uncouth and irregular methods, thorough training; and for want of discipline, loyalty and devotion to the physician, which give him comfort and support in the most trying hours of his life. A trained army was substituted for a huge militia band; confidence for uncertainty and doubt. All honor, credit, praise, and thanks to the noble women, who have proved the truth of the poet's assertion that "peace hath her victories, no less renowned than those of war." Think for a moment of the many aspects of the benefit which these women have bestowed upon the community. The first advantage which resulted from their labors affected the sick; the second, their families; the third, the physicians; and the fourth, thousands upon thousands of young women, who were not only willing to labor in the new field thus opened to them, but grateful for the opportunity afforded them. When the wondertul change was effected, the world stood amazed at the suddenness, completeness, and apparent ease with which it had been accomplished.

Nothing is further from my mind than the wish to charge the evils of the old system upon the kindly and good women who did their best to make it as efficient as they possibly could. Ah, I pathetically recall too many of these faithful and devoted old nurses with affectionate reminiscence, for this injustice to be possible at my hands! They were merely parts of a poor and inefficient system constructed and fostered by society and not by themselves. May their good deeds be remembered with gratitude and may their souls rest in peace!

Seventeen years ago I delivered an address on an occasion like this, to a graduating class of nurses, in which I pointed out to them the shortcomings which are commonly charged against the trained nurse. Time has so little changed the circumstances that I offer similar suggestions to you to-night, for the purpose of urging upon you the avoidance of pitfalls which will lie directly in your path. Do not be discouraged or cast down from their enumeration, but feel assured that they are brought to your notice from a sincere interest in your welfare, and an abiding hope that, when you encounter them, the words which you hear to-night may prompt you to recognize and avoid them.

1. It is very generally said that the trained nurse often gives so much trouble in the families into which she is called that the advantages of her presence are surpassed by the annoyance which commonly results from it in domestic affairs. Remember that you go to patients' houses at a time when they are deranged by sickness; that you are merely an employee in such houses, that every particle of trouble which you give will be registered against you, will work to your injury throughout the community in which you live, and by the patronage of which you must thrive.

2. We have arrived at a period in the world's history when it is no longer believed that disease is propagated in some occult and mysterious way. When measles, scarlatina, smallpox, or septicemia develop, they are now regarded as the results of disease germs which, attaching themselves to the bodies of individuals, or floating freely in the atmosphere, are wafted from person to person, as the pollen is carried from flower to flower. This entity, the disease germ, strikes down an individual, even as the bullet strikes down the soldier, by its own inherent power. Now these germs are readily carried from house to house, and from individual to individual by the clothing; the nurse who arrays herself in garments not susceptible of washing and thorough disinfection is guilty of criminal recklessness.

3. When you are called upon to nurse for an obscure and unknown physician, one perhaps, whose life has been passed in the depths of the country districts, beware how you presume to ignore him, to despise his authority, and to set your opinions up against his dicta. Remember that you are the nurse in the case, that a nurse's duty is to obey the physician's orders. Are you convinced that he is an ignorant and inefficient man? That is not your affair. Those who employ you employ him, and they employ you not to keep the physician of their choice in order, but to obey his behests, whatever they may be.

4. Regard no duty connected with your office as too menial for your hands; refuse no reasonable request which appertains to the duty of nurse; but render yourselves so perfect in the performance of the smallest details that they shall lose their menial aspect and appear worthy of your hands by reason of the skill which you display in ther performance.

If I proceed further I fear that you will ask yourselves, "Has he not yet done with this list of shortcomings, this array of faults with which, he says, our guild is charged?" Bear with me for one more and one very important piece of advice.

5. Let everything which you learn in the capacity of nurse in any household meet its tomb in your ear! Tell nothing good or bad concerning families in which you serve; for, if you talk of the good, the mention of the bad will assuredly follow, even as the "sparks fly upward." In times of illness the secrets of a family cannot be hidden from your ken; the closet doors are open, and the eyes of the midnight watching nurse cannot fail to see the skeletons which hide within! Can you suggest to me anything more contemptible, more deeply sunk beneath the dignity of womanhood, more repulsive to propriety, than the treacherous exposure of the poor bleeding wounds of sorrowing households to the public gaze and to the gossip's tongue?

An Eastern tale is told of a hakim who, coming forth from the Sultan's palace, was asked, "How does the Sultan?" "The Sultan sleeps," he re-

plied. In one hour from that time he was exiled from Turkey, and told that he had just escaped the bowstring because he had dared to tell the secrets of the Sutan's palace to the world. Learn as little as you can of the domestic affairs of households into the bosoms of which you are admitted, and that little keep within your breasts shut up, as secrets entrusted to your honor!

Let me in all seriousness sketch for you, with pen, not with brush, the type of a model nurse, relying upon a full and lengthy experience for the correctness of my work. She stands before me at this moment, not as one whom I have really known, but as one of a class which in my professional career has been a large one. She is a comely, wholesome woman, not pretty, not handsome, but blessed with an honest countenance, which says as plain as whisper in the ear, "You can trust me." For a long time I tried to find out why it was that she was so generally popular, not as a woman, mind you, but as a woman-nurse, and after abundant experience I decided that it was because she had a heart which was full of amiability, kindliness, loyalty, and truth. Of her attainments I have little to say, for she is, as a matter of fact, only equal to the average. I have found that average good enough for all my demands, and I have sometimes found some of the brightest, most talented nurses to be the least attractive and agreeable of women in the sick-room. My model nurse is quiet, not talkative, not boastful, not inclined to become very intimate with patients, patients' friends, or doctors, but polite and friendly with all of them. She seems to be impressed with the idea that she is a nurse, not a friend or companion. I will not tell you of her faithfulness to the sick, or of her loyalty to the physician; because those virtues are so very general among trained nurses. She has one peculiarity, which if any of you lack, you need not mourn, for it may readily be cultivated; it is a well-modulated and sweet voice. If she has to announce to family or physician that the patient will be dead within an hour, it mitigates the terrors of the awful news, and as far as this is possible lessens the inevitable shock of the announcement.

My nurse is now approaching the end of that career through which I have with so much interest watched her passing serenely onward, shedding brightness, courage, faith, and hope upon all who have come within the circle of her benign influence! There is no reason why any one of you should not accomplish all that she has done and at the end win the praise which I give to her.

And now, Graduates, in saying farewell, let me cordially and sincerely bid you Godspeed upon the useful and beneficent career which you have adopted. May your labors in the future serve to carry comfort, hope and health to many a suffering couch: may your efforts at maintaining yourselves as dignified and independent women meet with that success which energy and industry ever command; and may you at the end of well-spent lives have cause to look back upon the ceremonies of to-night and upon those whose hearts at this moment beat in kindly sympathy with you with pleasant and grateful recollections.

HEREDITY.*

BY J. W. KIERNAN, M.D.,

OF CHICAGO;

FELLOW OF THE CHICAGO ACADEMY OF MEDICINE; FOREIGN ASSOCIATE MEMBER OF THE FRENCH MEDICO-PSYCHOLOGIC ASSOCIATION; HONORARY PRESIDENT OF THE SECTION ON NERVOUS AND MENTAL DISEASE, PAN-AMERICAN MEDICAL CONGRESS, 1893; MEMBER OF THE INTERNATIONAL MEDICAL CONGRESS, 1901.

THE individual who comes into the world is, as Luys[1] remarks, but one link in a long chain unrolled by time whose first links are lost in the dim past. His ancestors are not merely his parents, but their progenitors likewise. These parents may have had ancestors of different type, with qualities seemingly absent in the child, which reappear in its descendants. Embryological demonstrations to the contrary notwithstanding, father and son are regarded as one being having two births, each time leading, as Moreau[2] (de Tours) remarks, the same life under the same conditions. Heredity is usually acepted as an expression of the inseparable entity of the individual. Man is regarded, not as a complex balance of cells organs, and resultant function, but as complete from the outset. This conception, fundamentally unsound, further refers the leading part to the parent who plays the least important rôle. The ovum, not the spermatozoon, is the factor in the development. Development regarded as settled and uninfluenced by environment until extra-uterine life has begun, pursues only an upward process.

Intra-uterine life, however, has an environment varying with shifting maternal conditions which governs fetal nutrition and development. All vertebrate embryos assume several forms successively, before definitely differentiating. Supernumerary organs exist in these common forms as phases of embryonic life. From this necessarily arises the united rôle of development (the creative phase of evolution) and degeneracy (the suppressed phase). Evolution of an organ or of its different parts is degenerative if it tend to the ultimate abolition of that organ or of its parts. Evolution is progressive if it tend to development likewise. Degeneracy and development, in the human fetus, passing successively through all vertebrate embryonic stages, play an essential part in the disappearance of lower vertebrate organs for the benefit of typically human organs. The balance between them governs proper evolution in intra-uterine life of the compound animal man. In embryonic development, organs, as De Moor[3] points out, do not always repeat successive phases through which they pass during evolution. While recapitulation of ancestral stages occurs, evolution often takes place

* Read in outline before the Section on Nervous and Mental Disease of the American Medical Association, June, 1901.

without leaving traces of some stages. This is especially true of complex organs arising by many lines of evolution converging in a single structure which becomes the seat of special functions or sets of functions. The neuron passes successively through stages corresponding to those of adult fish, frog, bird, and mammal. Here development consists of increasing cell complexity without formation of unnecessary rudimentary parts. The amount of assimilable nutriment for the fetus being fixed,[4] a struggle for existence results through the law of economy of growth by which, as Roux[5] has shown, less important structures suffer for the benefit of the organism as a whole. Through this law, cells surrender reproductive powers and other functions to secure greater specialization of one function for the benefit of the organism. Local atrophies, hypertrophies and degenerations hence are required to develop the child from the mass of contending embryonic possibilities. Potentialities of lower vertebrate structures and organs develop at certain stages in human intra-uterine life to retrogress in preparation for the next higher stage. To carry the organism through these peroids of stress, not only is an initial velocity given by heredity needed, but likewise favoring environment.

The initial velocity arises from factors furnished from the ovum and minor elements from the spermatozoon. The ovum, partly the product of female heredity, is largely affected by female environment up to the time of conception. To a lesser degree this is also true of the spermatozoon. The greater influence of the ovum is shown in the imperfect occurrence of parthenogenesis in even the highest vertebrates. Phenomena of certain ovarian cysts demonstrate this to be the case even in woman. The spermatozoon simply adds nutriment to the ovum, determining to a limited degree type of development, but only to a minor extent initiating this. Bisexual reproduction resultant on the law of economy of growth enables reproduction to occur with less waste of force and material than unisexual. The interests of the individual and the race in reproduction therefore conflict, as Herbert Spencer long ago demonstrated. Since it is impossible that these two forces should counterbalance, equilibrium must reestablish itself in orderly fashion. The two forces preservative of every animal group (the impulse of every individual to self-preservation and the impulse to the production of other individuals) must vary in an inverse ratio. One must diminish when the other augments. Degeneration is a process of disintegration, the reverse of development or integration. Hence, if the processes which complete and sustain individual life be termed individuation and those which aid formation and development of new individuals be termed generation, individuation and generation are necessarily antagonistic. The higher and larger organisms never reproduce unisexually, the lower and smaller organisms reproduce with marked rapidity by this method. Between these extremes unisexual reproduction decreases while size augments. When growth of the individual is rapid reproductive organs are imperfectly developed and inactive. Reproduction, hence, indicates decrease in intensity of growth and may cause cessation. Great fecundity is always attended by marked mortality. Each superior degree of organic evolution is accompanied by an inferior degree of fecundity. The greater the germ the less is the individuation and *vice versa*. The greater and more complex the organism, the less is the power of multiplication.

An exaggerated estimate of the significance of these facts led Weismann[6] to maintain that there was a specially organized living hereditary substance which unlike the substance composing the perishable body of the individual is, in all multicelluar organisms, transmitted from generation to generation. Here is obvious the old error of organism entity at conception mingled with a half truth as to type preservation.

In determining retrogressive change for advance two factors are in alliance against two others. Type heredity and family heredity or immediate atavism oppose distant atavism and immediate heredity. Atavism does not necessarily imply type degeneracy. From the conflict of these forces it is obvious that conditions favoring direct heredity can but seldom occur. The embryological basis of Weismann's hypothesis was the assumption that the first division of the cell or ovum was into body plasm and germ plasm. The phenomena of asexual reproduction shown in the experiments on invertebrates of J. Loeb[7] had thrown doubt on this assumption and had strengthened the results contradictory of Weismann, obvious in the experiments in reproduction of double monsters by E. C. Spitzka,[8] Dareste, Duval and others. The embryologic basis of Weismannism was completely demolished by experiments in the Naples Aquarium,[11] demonstrating that even when the cell divided sixteen times, separate cells, dissociated from the group, could pursue a separate existence and become well-developed organisms of the parent type. Weismann, forced to a partial though concealed abandonment of his central position, had admitted in his last work that "the origin of a variation equally independent of selection and amphimixis is due to the constant occurrence of slight inequalities of nutrition in the germ plasm. These variations are at first infinitesimal but may accumulate, and in fact they must do so when the modified conditions of nutrition which gave rise to them have lasted for several generations. But although it is improbable that individual variability can depend on a direct action of external influence upon the germ cells and their contained germ plasm, which must be very difficult to change, yet it is by no means to be implied that this structure may not possibly be altered by influences of the same kind continuing for a very long time."

Disturbance of the balance governing embryo-

logical development causes reversion to the excessive fecundity of the earlier biological types. Such reversion produces conditions summarized half a century ago by Moreau (de Tours) into the following categories: First, absence of conception; second, retardation of conception; third, imperfect conception; fourth, incomplete products (monstrosities); fifth, products whose mental, moral and physical constitution is imperfect; sixth, products specially exposed to nervous disorders in order of frequency as follows: epilepsy, imbecility or idiocy, deaf-mutism, insanity, cerebral paralysis and other cerebral disorders; seventh, lymphatic products predisposed to tuberculosis and allied disorders; eighth, products which die in infancy in a greater proportion than sound infants under the same condition; ninth, products which although they escape stress of infancy are less adapted than others to resist disease and death. The absence of conception is generally due to intense cellular proliferation in the ovum.

Degeneracy hence, so far as heredity is concerned, is not an introduction of new factors in the shape of acquired effects, but reversion to lower types of cells, organs and functions. Conditions, as Bland Sutton[9] shows, pathological in one animal are often physiological in another. As embryology demonstrates, conditions physiological at one phase of embryonic development are pathological at another. These conditions frequently result moreover from destruction of inhibitions which permit functions to exceed normal limits. Pathology consists, as Virchow[10] shows, merely in the introduction of a new factor into the organism. Change from one species into another either in individual animals or plants or individuals or their tissues cannot take place without anomaly, since without anomaly such new departure is impossible; the physiological norm hitherto subsisting is changed, which change cannot well be called anything but anomaly. Formerly an anomaly was called pathos. In this sense every departure from the normal is a pathological event. Such pathological event may be caused by an external force, a chemical substance or a physical agent, producing in the norm an anomaly (pathos). This may become an hereditary foundation for characteristics propagated in a family. These belong to pathology, though they produce no injury. Pathological does not mean harmful nor does it indicate disease. Disease in Greek is *nosos* and it is nosology that is concerned with disease. The pathological may sometimes be an advantage to its inheritor.

The Weismannian doctrine, anent non-inheritance of acquired characters, may be true if the sense in which acquired is ordinarily employed be accepted, especially since, as Weismann admits,[12] conditions like tuberculosis may produce "habits" in the ancestor which may be transmitted to the descendant. These "habits" consist in structural peculiarities, such as narrowness of the chest, etc. The conflict between the extreme hereditary doctrine and the Weismannian denial of inheritance of acquired characters or variation, has been harmonized by Roux, who shows that, by the law of economy of growth, there occurs an internal or physiological struggle for existence between organs, cells and protoplasmic molecules of the organism. Hence in heredity surrounding forces are always necessary, not simply the condition of activity by an essential element of the final product.

How far initial velocity from heredity may carry the product of conception is determined by the intensity of the initial velocity and the nature of the environment at periods of intra- and extra-uterine life. At such periods through suppressive economy certain parts in the evolution of organs disappear and in the evolution of organisms certain organs. Since disappearing and developing tendencies necessarily center around the time when functions are to be lost by the disappearing and others gained by the developing, periods of stress appear around which occur the struggle for existence between parts of organs and between organs themselves.

The human embryo has potentialities of ancestral gains as well as lower vertebrate possibilities. It does not attain to the full the potentialities of its ancestral gains, since gains of the individual under the law of individuation are sacrificed to race reproduction. The child with its relatively enormous head, its large protuberant abdomen, its small chest, short feeble legs, comparatively vigorous arms, smooth almost hairless skin, large liver, kidneys, thymus and suprarenal capsules, presents, as Havelock Ellis[13] remarks, an anatomical picture distinct from that of the adult. The indications of the child's physiological and psychical life are in the same direction. Anthropoid apes at an early life period are unlike the adults. The young anthropoid is comparatively human, while the adult is comparatively bestial. The young ape has a smooth globular head and relatively small face like man. The profile is more human, with little prognathism, the skull base is more humanly formed than that of the adult and the brain is relatively very much larger. The gorilla fetus differs from the adult in a much larger head, a longer neck, a more slender trunk, shorter thumb and greater toe. The head is more globular, the face less prognathous and the hand more man-like. Here the fetal gorilla approaches man. The adult rapidly develops into a condition far removed from this man-like state. The brain becomes relatively very small, the skull becomes hideous with huge bony crests, outstanding superciliary ridges, projecting jaws and receding chin. The dark hairy body becomes more bestial. The female ape remains midway between the infantile and the adult male condition.

So far as man is ape-like he resembles the infantile ape, not the adult. Man falls away more and more from the specifically human type of early years. The ape in a short life goes further along the line of premature senility. He starts in

life with marked human endowment, but soon falls far from it. Man starts in life with a still greater endowment but to a lesser extent falls from it, in adult life approaching the ape. Up to and soon after birth the higher animals, like the apes and man, have for a time rapid vigorous movement upward in zoological evolution, his fetal or infantile development, ceasing to be upward, is later so directed as to answer to life wants of the species. Henceforth and throughout life, a development of lower characters, a slow movement toward degeneration and senility occurs which is necessary to ensure preservation and stability of the individual and species. Fetal evolution sheltered from the world is in an abstractly upward direction. After birth, further development is a concrete adaptation to the environment conflicting with upward zoological movement. The infantile condition in man and ape approximates most the human condition. The adult condition approximates the anthropoid. The human infant has, in exaggerated form, the chief distinctive human characteristics, large head and brain, small face, hairlessness and delicate bony system. The adult form is erroneously assumed to be more highly developed than the infantile. From the standpoint of adaptation to environment the hairy, large-boned, small-brained gorilla is better fitted to survive in the struggle for existence than his delicate offspring. From a zoological point of view anything but progress occurs.

From about the third year onward in man growth, though a necessary adaptation, is to some extent growth in degeneration and senility. By it man is brought somewhat nearer the apes. Among the higher races such growth is less marked than among the lower. The child of many lower races is scarcely if at all less intelligent than the child of the higher. As he grows up the lower child becomes stupid and obtuse and all social life falls into hide-bound routine. The higher retains much child-like vivacity. The highest human types represented in typical men of genius strikingly approximate the child type.

Initial hereditary velocity is apt to be affected by maternal environment at two great periods of intra-uterine stress, like the senile (or simian) period (which occurs four and a half months after conception) and the period of sex differentiation.[14] Arrested development at the senile period of intra-uterine life by any process, which checks evolution, may influence extra-uterine development. When produced by syphilis (to which the senile appearance of new-born children is so frequently due) the child, because of organs which have undergone premature senescence, fails to pass through the first dentition or readily falls a victim to infections. Precocity, whether intellectual or physical, expresses arrest of development at the senile period which causes the child to pass through the period of growth and senescence rapidly. The truth of the popular opinion of precocity (early ripe, early rotten) is very demonstrable. Of six cases[15] of early puberty in boys, one, virile at one year, died senile at five. A girl menstruated at two, became pregnant at eight, a grandmother and senile at twenty-five. Premature senility may evince itself in arterial atheroma at the periods of extra-uterine stress. This has been observed frequently in the children of vegetarians and after the essential fevers.

If initial hereditary velocity be tinctured with senility at this period, the individual fails to reach the high promise of the child. This often results from the struggle for existence between the reproductive system (representing the race) and the central nervous system (representing the individual). The senile tendency is therefore aided by gains of the reproductive system at the period of sex differentiation. Sex, as Drusing[16] has shown, is not inherited, but results from various factors acting not only at the time of impregnation, but at various times thereafter. Long after impregnation, when the embryo is already developed, nutrition is still influential and may change the tendency even after sexual organs have developed. Poor maternal nutrition may arrest female development, causing reversion to the male type. The psychic side of sexual differences should normally, as it often does, remain undifferentiated until adolescence. Adolescence is affected by atavistic tendency to simian senility, which implies its early onset.

The psychic phase of instincts so fundamental as the reproductive instinct may appear even when there is congenital absence or rudimentary development of organs upon which its expression depends.[17] Psycho-sexual manifestations may remain indifferent until adolescence, may be of homosexual type (the same sex), may be of heterosexual type (opposite sex), or may be hermaphroditic (both sexes). Three conditions (infantilism, masculinism and feminism) and a mixed state may result from arrested development before, at, and after sex differentiation. As the inferior organs and sex nerves are differentiated ere the psychic phase, this side of sex may be determined only in extra-uterine life. All three conditions are arrested developments of child type potentialities.

The struggle for existence between the central nervous system and the reproductive system usually occurs with greatest intensity between fourteen and twenty-five. The break-downs at this period are expressed in hebephrenia, dementia præcox, and other psychoses of puberty and adolescence. From the puberty struggle for existence between the chondrocranium[18] (primitive skull developed from the vertebræ) and its later type as supplemented by the dermal bones, the nervous system may take a distorted ply, arresting bodily, nervous and mental development. Infantilism arrests the potentialities of the child. Body and face remain at the child-point, or body and nervous system are checked, or the nervous system or certain organs alone are affected, while the body goes on to full development. The

face may be arrested at any period from birth to puberty, hence many persons retain a youthful appearance throughout life. These people are often vain, egotistic and of weak mental and moral stamina. The females are often sexually anesthetic, harlots, and allied beings, like prurient prudes, hysterical reformers or gossip-mongers.

As the female type most nearly approximates the potentialities of the child, arrests of its development may result in masculinism and feminism. The female may proceed so far in development as to have female organs and their functions, while retaining predominant traces of the male. The male may proceed toward the female type, but ere full sex differentiation occurs further development has been checked and the male type becomes predominant. Arrested development may take place at any stage in embryogeny. The male preserves female breasts while normal in other respects or presents crypt orchidism or sloping shoulders while otherwise masculine. His nervous system may take such a ply that at puberty the sexual instinct is feminine in type. This may extend merely to extreme modesty toward males, and intense liking for female occupations or a disgust for those of the male.[19] In the female, identical conditions occur.

The sexo-psychic side is sometimes entirely dormant until adolescence. Education, then, may give sex direction rather than innate tendency. A male underwent arrest of development in evolution toward the female type, and had been brought up as a girl. "He" had pleasing womanly qualities and was married thrice to intensely devoted husbands. The real sex was not suspected until necropsy demonstrated that the supposed woman was a man. Where the nervous system has taken one sexual ply while the body has taken another, beings result which need careful special training during infancy, childhood and adolescence. Sometimes these beings present in addition to the sexual distortion, mental defect or moral obliquity or both.

In higher and lower races tendency to sex predominance is in different direction. The lower race female resembles the male of her race. The man of the higher races resembles in mentality and pelvis the woman of his race. This is partly due to intrusion in the course of evolution by the male on female occupations. All occupations other than war, hunting and fishing, were created by woman.[20] The higher race male, while taking on female intellectual and esthetic qualities, retains male mental and physical sexual characteristics which, in accordance with evolution, are less explosively manifested than in the male of primitive races. While sex differentiation as to special sex organs may not be arrested at this period, still normal sex development may be so affected as to produce premature sexual appetite expressions evident in generalized pleasure[21] rather than conscious sex direction. Such often occur in healthy girls under one year without genito-urinary irritation. This generalized pleasure underlies that auto-erotism of future life into which, as Havelock Ellis has pointed out, the sexual emotion may be absorbed and even entirely lost in self-admiration. This Narcissus-like tendency of which the normal germ is symbolized by the mirror is sometimes found in men. In women it occurs sometimes in association with an attraction for other persons to which it is normally subservient. In the extreme form there is indifference to sexual gratification or admiration of the opposite or the same sex.

Among factors usually accepted as part of heredity are congenital influences arising from maternal environment during pregnancy. Pregnancy, according to Virchow's definition, is pathological so far as the mother is concerned, since it disturbs the physiological balance previously existing in her. With recurring pregnancies the reaction to this pathological factor tends to decrease unless aided by other influences. Since the physiological balance of the mother is disturbed she becomes more susceptible to outside influences. From such susceptibility variations in fetal environment result. These underlie the so-called "maternal impressions." The fetus very decidedly reacts to sensory impressions on the mother. Women, as Féré[22] has shown, often in an ordinary dream producing but very moderate excitation, not as a rule interrupting sleep, are awakened by fetal movements. The dreams have nothing of the nightmare character, but are ordinary phenomena of sleep. Maternal mental changes hence excite fetal motor reactions which, like sensorial excitations, are stronger in the fetus than in the mother. The mechanism of these is due to unconscious movement of the uterine muscular wall.

Such factors entering into fetal environment influence progress. Maternal strength hence plays an important part. Much alleged heredity, charged to paternal defects, arises from the influence of these on maternal nutrition. Albeit paternal deficiencies are present at marriage, the influence of these is very often not obvious until one or more children have been born. The influences of paternal defects in producing maternal neurasthenia must therefore be taken into account.

Most hereditary defects are expressions of weakness along lines of least resistance and not due to direct inheritance. Epilepsy is often an expression of inability to pass periods of stress without motor explosions. It therefore expresses an arrest of development at certain phases in childhood. Through ignorance of this fact convulsive disorders of childhood often pass into epilepsy. Through that law of the nervous system whereby nerve action, once occurring, has a tendency to recur, habits are established and likewise quasi-periodic disorders like epilepsy. Weismann sciolistically charges epilepsy to microbes, explaining its greater maternal transmission by the exceedingly crude notion that since the ovum can carry more microbes than

the spermatozoon, epilepsy occurs more frequently from maternal heredity. The "habit" transmission of Weismann, however, explains the origin of epilepsy more logically than his bacteriological Pegasus.

From the standpoints of embryology, biology and pathology, direct inheritance of aught but systemic vigor or weakness, taking the line of least resistance, may be doubted. Weismann's position, so limited, seems justifiable.

The impact on the initial velocity of heredity enables it to pass through or be arrested at the periods of stress. The effects of such arrests are determined by the points of least resistance. Such points of least resistance are transitory structures like the hair, ears, teeth, jaws, as well as the later acquirements of the race.

Under the law of economy of growth, arrested development may produce excessive growth or atrophy or both. In this way a scion of degeneracy often gains in nervous system and brain what is lost elsewhere. Whether a pathological result is beneficial or detrimental must be determined by the law of relativity, not by the pathological event itself.

That acquired defects sometimes exert an influence in determining the line of least resistance is shown by the results of circumcision. Medical opinion to the contrary notwithstanding, Jews are born with a partially-developed or absent prepuce so frequently that no comparison can be made with the non-circumcising races. The centuries old Talmudic discussion anent Jewish Ritual[23] to be followed in cases where the boy is born without prepuce significantly demonstrates the frequency of this, since theologians do not cross a theological bridge in ritual until they come to it. Furthermore, conditions resultant from the "habit" inheritance admitted by Weismann provide an ample line of least resistance sufficiently explicatory of the seeming inheritance of acquired characters.

This is excellently illustrated in a family whose history I reported four years ago.[24] The family originated in the Eastern States, but branched southward and westward. A farmer lived twenty miles distant from his nearest neighbor whose only daughter he married. She led a lonely life till her courtship at the age of twenty-eight by the farmer, then three years younger. The farmer married her for $200, after having impregnated her. He then found lead on his farm and went to a city. A stock company bought his farm and launched him into the stock market, where he made money, more as a cunning tool than adventurer. He became a high liver, gouty and dyspeptic and died from gouty kidney at the age of seventy years. The couple had five children. The eldest child became a "Napoleon of Finance," had his father's cunning and died wealthy within the pale of the law. He married a society woman; the last scion of an old family. The second child (a daughter) was clubfooted and early suffered from gouty tophi. She married a society man of an old family who had cleft palate. The third child (a daughter) had congenital strabismus. She married a man who had irregular migraine. The fourth child (a daughter) was normal. She married a thirty-year-old businessman, in whom ataxia developed a year after marriage. The fifth child (a son) was ataxic at eighteen. The scions of the "Napoleon of Finance" and the society woman were an imbecile son, a hysteric, a female epileptic who had a double uterus, a nymphomaniac, and a society man who wrote verses. The cleft-palated society man and clubfooted woman had triplets born dead and a strabismic, migrainous son who, left penniless by his father, married his cousin, the nymphomaniac daughter of the "Napoleon of Finance," after being detected in an intrigue with her. The migrainous man and strabismic daughter of the farmer stock-broker had a sexual invert masculine daughter, a daughter subject to periodical epistaxis, irrespective of menstruation, as well as chorea during childhood, a normal daughter, a deaf-mute, a phthisical son, a cloacal daughter, an ameliac son, a cyclopic daughter born dead and a normal son. The sexual invert married the versifier son of the "Napoleon of Finance." The progeny of the normal daughter of the farmer stock-broker and the ataxic man were a dead-born sarcomatous son, a gouty son with early tophi, twin boys paralyzed in infancy, twin girls (normal), a normal son, and a son ataxic at fourteen. The progeny of the nymphomaniac and her strabismic, migrainous cousin were a ne'er-do-well, a periodical lunatic, a dipsomaniac daughter (who died of gastric cancer), deformed triplets who died at birth, an epileptic imbecile son, a hermaphrodite, a prostitute, a double monster born dead, a normal daughter, and a paranoiac son. The ne'er-do-well married his epistaxic cousin. The gouty son of the farmer's normal daughter married the hysteric daughter of the "Napoleon of Finance." They had a son born with unilateral asymmetry, a prostitute, dead triplets, a male sexual invert, a color-blind daughter, and a normal son. The color-blind daughter married a paranoiac grandson of the "Napoleon of Finance." The progeny of the sexual invert and the versifier (who were soon divorced) were a periodical nymphomaniac, who had some artistic and literary talent, and a son, who died of gastric cancer. The scion of the ne'er-do-well and the epistaxic woman were a moral imbecile, a "bleeder," a stammering daughter who had uvula deformity, a deaf-mute cryptorchid, dead-born triplets, an infantile paralytic son and dead-born quadruplets. The progeny of the paranoiac and his color-blind cousin were an exophthalmic daughter, an epileptic cryptorchid, a cleft-palated imbecile with a cloaca, dead-born quadruplets, an idiot boy, and a "bleeder."

Among the factors influencing points of least resistance are toxic products from maternal autointoxication and toxins of various contagions and infections. Decades ago alienistic biologists observed that similar degeneracy stigmata re-

sulted in the offspring of the tuberculous, syphilitic and neuropathic. During the reaction from the early views as to the intensely specific nature of luetic consequences, which the elder Fournier led, it became evident that the non-specific effects of luetic heredity were as marked as the specific. The ground-work for this view was experimentally demonstrated by Charrin and Gley[25] in researches upon the influence of parental reception of virus on the offspring. The bacillus of blue pus or its toxins was inoculated. The results were not uniform. Most frequently, sterility, abortion or birth of progeny ensued. The offspring, in rare instances, survived; more rarely still were they healthy. Rabbits born of these undeveloped animals sometimes had enormous epiphyses, the diaphyses being shortened. Of five rabbits born of one pair inoculated, two were normal and a third (whose ears were rudimentary) died in a few days. The ears in the other two were fragmentary with jagged upper edges. The tails were two centimeters long. The external orifice of the vagina (one rabbit was male and the other a female) was oblique. One of the limbs (the hind in the male and the fore in the female) was much shorter than its fellow and ended in a stump, there being no foot nor toes. The results of these experiments are borne out by careful analysis of the effect of syphilis, tuberculosis and allied contagions on the offspring. As E. Fournier[26] and others have shown these may have nothing specific *per se*, but are evinced in congenital inferiority of constitution, of temperament, of vital resistance or in retardation, arrest or imperfection of development, mental or physical or in manifest organic changes; either organ malformations or monstrosities. Toxins produced by germs or poisons produced by maternal nutritional defects may cause arrest, retardation, or imperfection of development of children of otherwise healthy mothers suffering from contagions and infectious or nutritional disorders or defects just precedent to, or during pregnancy, or during lactation. During periods of stress, moreover, toxins or allied substances generated in the child's organs may cause bony and dental arrests, retardations and imperfections of development, so frequently noticed after scarlatina, pneumonia, crebrospinal fever, etc., as well as in rickets and in allied conditions during infancy and childhood. Here two factors are evident, the weakened constitution of the ancestor which, as even Weismann admits, may affect the germ plasm, and, second, the toxemic state that affects fetal nutrition. Strictly speaking, this last cannot be called a hereditary factor, albeit it results from weakened maternal nutrition.

The origin and character of defects and gains depend so far as beneficial or deteriorating influence is concerned upon the law of relativity. A lengthy discussion of the relation of genius to degeneracy has resulted from non-recognition of this factor. Genius, according to Huxley,[27] is innate capacity of any kind above the average mental level. From a biological point of view a genius among men stands in the same position as a "sport" among animals and plants and is a product of that variability which is the postulate of selection, both natural and artificial. On the general ground that a strong and therefore markedly abnormal variety is, *ipso facto*, not likely to be so well in harmony with existing conditions as the normal standard (which has been brought to what it is largely by the operation of those conditions), a large proportion of "genius sports" are likely to come to grief physically and socially and the intensity of feeling which is one of the conditions of genius is especially liable to run into insanity.

Genius sometimes has such relationships, but they are not necessary to it. The fact that the highest promise of the child type is shown in the adult by the genius emphatically destroys the claim that genius is still a "sport."

The genius, as Herbert Spencer[28] has shown, is, together with the whole generation of which he forms a part along with its institutions, its language, manners and multitudinous arts and appliances, a resultant. Genius depends upon the long series of complex influences which have produced the race in which it appears and the social state into which that race has grown. All the things of which the genius is the proximate initiator have their chief causes in the generation from which he descends. The more the "sport" appears in the genius, the further he departs from race types in the direction of degeneracy. Not in the genius, but in the "sport" element is shown the deficiency. The genius is an expression of race gains that have survived intra- and extra-uterine periods of stress as well as race senescing influences.

Environment during puberty and the formative periods determines properly-balanced development of genius. Undue intrusion of the reproductive element sacrifices the individual to the race. This element marred the otherwise complete self-culture of that excellently-balanced genius, Goethe, who was *facile princeps* as poet, philosopher, experimental scientist and sociologist. The influence of environment crushes out many a potential Goethe, as Ruskin has shown. The law of economy of growth produces the genius whether well balanced or of "sport" type.

How far pathological events may favorably influence the future at plastic periods of heredity is shown in Cuvier and to a lesser extent in Sir Walter Scott. Hydrocephalus here prevented premature closure of all sutures permitting dermal bones to supply chondrocranial deficiencies and favoring replacement of cavities which, while not functionally active, gave full scope to nerve tissue. Here a pathological event proved destructive of degenerating factors, preventing retrogression of brain tissue resultant on suture closing.

Heredity obeys no absolute law in details, but is governed by a struggle between contending forces. Initial hereditary velocity is an important factor, but so likewise is intra- and extra-uterine

environment, especially as constituted by maternal strength during intra-uterine periods, during periods of nutrition by the mother, and during periods when the child is under maternal training. Heredity is a prophecy of what *may* be, not a destiny which *must* be.

THE LIMITATIONS OF MEDICAL THERAPEUTICS.[1]

BY FRANK BILLINGS, M.D.,
OF CHICAGO.

The successful application of remedies to disease has not kept pace with the immense advancement in the knowledge of pathology or of diagnosis during the last ten years.

The instruments of precision in diagnosis, especially the microscope and the various reactions which may be obtained in the bacterial and chemical laboratories, enable one to separate and recognize the differences between the infectious fevers and various other diseases of organs of the blood.

Thus, typhoid fever, malaria, plague, diphtheria, epidemic meningitis, cholera, epidemic dysentery, amebic dysentery, tuberculosis, gonorrhea, tetanus, and relapsing fever may all be recognized with certainty, not only by the clinical course, but by the microscopical examination of the blood and of the exudates, transudates, etc., supplemented by laboratory bacterial and chemical examinations. Of the various diseases not infectious in character, or at least not now recognized as infectious, and the general diseases which affect the blood especially, the present methods of examination enable us to more certainly diagnose and to separate the one from the other.

For instance, the blood is now fairly well understood so far as its morphology is concerned. We recognize ordinarily the primary and the secondary anemias; we differentiate the different types of leucemia; the modern methods of examination of the stomach enable one to recognize with reasonable certainty ulcer and carcinoma, and to differentiate them from the less severe chronic gastritis.

This great advance in our knowledge of the cause of disease and the improved methods of examination which enable us to recognize more certainly and to differentiate disease have had their influence on therapy. This influence, however, has been chiefly in the application of the principle of the production of an artificial immunity and at the same time the introduction into the body of curative antitoxins.

We may be justly proud of the use of the antitoxin serum of diphtheria, of tetanus, of plague, of dysentery, of cholera and of the antivenomous serum in intoxication due to wounds of poisonous serpents, in the cure and prevention of these several diseases. The application also of prophylactic fluids, such as that of Haffkine for plague, and the use of like preparations of fluid for other diseases has been followed by equally good results as compared with the serum-treatment in the prevention of disease. These notable results justify the belief that we shall some day apply the same principle to the treatment of most, if not all, of the infectious diseases.

Until the discovery of these practically specific means of treating the infectious diseases, the only remedies that in any way resembled specific drugs in their effects were mercury and quinine. Empiricism taught us that mercury was almost uniformly curative of syphilis and the specific action of quinine in malaria came in the same way. Even now the accurate knowledge which we have of malaria has enabled us to apply quinine to the relief of the infection more rationally and perhaps with better results than before.

The more exact knowledge we possess of the infectious diseases and of the local and chronic disease processes of the body has enabled us to apply specific medication in a limited way only. If we add to this the drugs quinine and mercury, which empiricism has shown to be practically specific, it still leaves an immense field in medicine in which the application of curative drugs is based upon insecure grounds. The application of drugs in this field can never be exact. Therapeutic practice in consequence must vary and differences of opinion arise in the future as they have in the past. It is to this field of therapy that I especially desire to direct your attention and to say something of its remedies.

For purposes of description I shall divide therapists into three classes to arrive at something definite concerning the limitations of medical therapy, and I shall take up the theories and practice of each one of these three classes.

In the first place I should name the nihilists in therapeutics. To this class belong those among us who are materialists in medicine. The man who works much in the dead-house and in the pathological laboratory and sees with the naked eye or the microscope the morbid changes which occur in organs finds it hard to believe that these conditions can be removed or even modified by drugs. This belief is further strengthened by the

[1] Address on Medicine delivered before the Ohio State Medical Society, at Cincinnati, 1901.

fact that the infectious diseases are self-limited, and, with the exception of malaria and syphilis, have not been influenced in the past by the application of medicines. The surgeon, too, whose field of work is along mechanical lines is apt to lose confidence in drugs as curative agents. His belief or faith in drugs is modified by his operative experience. The disease processes which in some instances his knife so readily removes, he finds it hard to believe may be much modified or even removed by the rational use of drugs. He does not understand that the morbid changes do not kill, but that it is the result of the morbid changes upon the functions of the organs which is disastrous. As an example, chronic interstitial hepatitis rarely, if ever, of itself, kills. The amount of liver tissue left even in extreme atrophic hepatitis is enough to maintain life. The invalid dies because of toxemia due to the loss of the full modifying effect of the liver upon the food-products which pass through it, or to the mechanical effects of the contraction of the cirrhotic tissue upon the venous radicals and the consequent injurious effect upon other organs and also upon the supervening dropsy.

Every rational physician knows that he may not modify the true cause, the liver cirrhosis, but he may materially modify, by proper remedies, the toxemia and the venous stasis and thus relieve suffering and prolong life.

Under the second class of therapists, I would place the theorists. The great majority of us practise under this head. The theorists treat symptoms or the disease, not the individual. He looks upon a disease or even a symptom alone as an entity, which is to be cast out by medication, as devils and evil spirits were in past ages cast out by incantation. He is an extremist, as much so as the nihilist. He looks for specific effects from drugs. Fever from all causes he fights with antipyretics and is happy if the temperature is lowered by the drugs used regardless of the natural course of the disease. Cough, whether of bronchial, of cardiac or of nervous origin, is combated because it is a cough and by similar remedies in all cases.

A chill calls for quinine, whether due to pyogenic cocci, malarial plasmodia, or what not. Anemia calls for iron, whether it be due to malignant disease, faulty hygiene or an unknown cause. This is the therapy of not only our own practitioners, but also that of the physicians we are pleased to term "irregulars." These we hold up to ridicule because of the dogmas they maintain of the specific application of certain remedies to symptoms.

Furthermore, many of the books on materia medica and therapeutics are so arranged that after the exposition of the forms, preparations and physiological action of a drug, there follows a list of the various symptoms and diseases in which it may be used advisedly. This form of practice is still further stimulated in the present day by the elegant, palatable and sightly preparations which the manufacturing pharmacist presents to the practitioner.

In the commercial world the supply follows the demand of a commodity. To the busy country physician, who must often compound his own prescriptions, the preparations of the manufacturing pharmacist were a boon. For this aid, and for the presentation of simple preparations in a presentable form, must we acknowledge thanks. But the manufacturing pharmacist ceases to be our helper when he attempts to present preparations in an elegant form when by so doing he renders them inert. Of what value are most of the tinctures and fluid-extracts in the form of tablet triturates? And if bad in simple form, how much worse if presented as a compound of two or more fluid preparations in a tablet, even if labeled the favorite prescription of some eminent practitioner as a "heart tonic," "laxative," "antidyspeptic," "antipyretic," etc., etc. What, too, of the syrups, elixirs, pills and mixtures with copyrighted names which are presented as specific "cure-alls"?

The pharmacist assumes when he presents to us these compounds, which for all practical purposes are patented, that we do not know enough to prescribe. Yes, he even says we are not able to diagnose a disease, for upon the label is often printed the symptoms for which the compound is a specific.

Let us give credit for all that the manufacturing pharmacist has done for us. We want elegant, sightly, palatable preparations. Let him give them to us, but let it be in forms which will not lessen the virtue of the drug and in simple not compound preparations.

I would name the third class of therapists rationalists. The practice of rational therapy is based upon a thorough knowledge of disease. This includes a knowledge of the pathology, the morbid anatomy, the clinical course and the recognition of the disease by means of all the modern methods and means of diagnosis. Experience is necessary to make a rational therapist. One must have the opportunities to observe the natural course of disease. Books will not afford this. Hospitals give one the best opportunities, but in private practice, in both the country and city, abundant material is at hand to study the natural development and course of disease.

He will make the best therapist who will use the means at his command to recognize the usual and unusual phenomena of disease. In addition to the organs which Nature has given him, the physician has at his command, at comparatively little cost, the modern instruments of precision in diagnosis which may enable him to become very proficient in the recognition of disease processes.

The knowledge thus obtained grows very rapidly and it is true, I believe, that the degree of acquaintance with disease bears an inverse ratio to the use of drugs. A knowledge of pathology and of morbid anatomy must teach one to use drugs sparingly and rationally. With a mental

picture before one of the morbid anatomy of a given disease, the rationalist does not attempt the frequently-impossible removal of the disease, but does try to modify the future development of the process and the results of the disease upon the other important organs of the body.

In surgery, cleanliness has made operations possible upon almost every organ of the body. For years the surgeon used the so-called antiseptic drugs in an attempt to secure freedom from infection in operative wounds. It required a long period of time to teach the surgeon that drugs were not necessary and that true cleanliness meant the use of pure water as an agent to purify operative fields, instruments and dressings. In midwifery, too, the former horrors of childbed have been removed by cleanliness. So true is this in both surgery and obstetrics that infection after operation or childbirth is looked upon as a grave blunder of operator, assistant or nurse in the matter of cleanliness.

In medicine cleanliness is just as important as in surgery. Just now the majority of us do not pay so much attention to it as we should. Medical cleanliness may be obtained, as in surgery, by the use of pure water as a drink, by the various forms of baths, antiseptic-mouth and throat-washes, lavage of the stomach, colonic flushes, etc. These measures of cleanliness not only lessen the element of external and internal infection, but also modify the results of the infection or the intoxication from which the patient suffers in consequence of some general infection or organic, chronic disease. Cleanliness should extend, too, to supplying the patient with pure air and uncontaminated, unadulterated food. These hygienic measures may not be classed with drug-therapy, but if practised will have a definite relation to the use of drugs, inasmuch as it will be found less necessary to prescribe drugs when medical cleanliness is practised. The drugs which the rationalist will use in this event will be directed to an attempt to meet emergencies when they arise in the course of the acute infections, or with the object of forestalling a possible accident, which his experience of the clinical course of disease has taught him may occur. He knows that there is no drug which will shorten the course of the infectious disease, with the exception of quinine in malaria and mercury in syphilis. This does not apply, of course, to the few specific sera. Unhappily, these are still few in number. The principle of the antitoxin treatment has been firmly established, and it is reasonable to hope that we may at no distant day command a specific treatment for all the acute infectious diseases, as we now do in diphtheria, the plague, tetanus, the intoxication due to the bites of venomous serpents, and probably also cholera and epidemic dysentery.

In the local and chronic diseases rational therapy applies as in the acute infectious processes. Here a thorough knowledge of the morbid anatomy of the clinical course and of the interaction of organs and parts of the body is absolutely essential to a rational therapy. Take, for example, a case of chronic interstitial nephritis. The treatment should be based upon the cardio-vascular integrity, upon the total urinary excretion, and upon the nutritional condition of the patient. Empiricism has taught us to use, in this form of chronic nephritis, digitalis, iron and some form of saline diuretic like acetate of potassium. These drugs are often united in a mixture and too often does the unthinking physician prescribe them when the diagnosis is established.

The rationalist would study the cardio-vascular system, the urinary output, and the nutrition of the patient.

If the balance were good he would not prescribe drugs, but would establish a hygiene in the form of diet, water as a diluent drink, proper clothing, and general conduct of life which would tend to maintain this balance of proper integrity of heart, urinary excretion and bodily nutrition.

If drugs were subsequently necessary he would give only such as were necessary to reëstablish the proper balance. Perhaps digitalis would be necessary at one time. Iron, too, perhaps should anemia occur, or, if not iron, some other hematinic, and, if water was not sufficient, perhaps a medicinal diuretic would be prescribed.

Thus the rationalist treats the individual and not the disease.

Nihilistic therapy is not justified by the experience of the past nor by present knowledge in either private or hospital practice. Nihilistic therapy and the symptomatic drug-treatment of the theorist are opposite extremes of practice. Both are wrong and both are supported by ignorance—a want of knowledge of a different kind, it is true.

Clearly, there is a marked limitation in drug-therapy, but still there is a drug-treatment which, if rationally applied, will be of much aid to the physician in combating disease and in alleviating human sufferings.

A HISTORY OF THE ARMY POST EXCHANGE OR CANTEEN.

BY DUNNING S. WILSON, M.D., PH.D.,
OF LOUISVILLE, KY.

The Army Post Exchange began its history in 1883 as an experiment at Vancouver Barracks by Col. Morrow, and its gradual adoption (1889-1891) throughout the Army has been the work and study of years.

Regulations governing the Canteen had been issued from time to time as arising circumstances required, until a thoroughly practical basis had been reached which was conceded by the vast majority of Army officers to be conducive toward the maintenance of law and order in the regiments. We see that the adoption of the Army Post Exchange was a matter of growth and came about only after careful investigation by men interested in the welfare of the Army. In 1895 the Exchange Regulations were clear and unmistakable in their interpretation and none, who read

conservatively, can claim that it was a promulgator of lawlessness.

It is evident from the above data that the Canteen has existed for over fifteen years, being tried for five years or more prior to its official recognition in 1889, and evidence, backed by statistics, goes to show that drunkenness, alcoholism and desertions have slowly but surely decreased and that the Army Post Exchange has been the most potent factor in bringing about this happy result.

At the Fifty-fifth Congress a bill was introduced with a view to abolishing the Canteen, but, owing to faulty construction, it did not accomplish its object. In this connection I would like to refer to the action of the Committee on Temperance of the Methodist-Episcopal General Conference in session at Chicago, May, 1900, which reported resolutions censuring President McKinley for accepting and acting upon the decision of Attorney-General Griggs that the anti-canteen law as passed by the Fifty-fifth Congress did not prohibit the sale of liquors. It is unnecessary to defend General Griggs for his opinion and, had the Temperance Committee carefully read and digested the Attorney-General's decision as given to the Secretary of War, they would scarcely have taken it upon themselves to attack the action of the President; as it was they only succeeded in making a display of ignorance in regard to legal opinions. General Grigg's decision as presented to the Secretary of War is a masterpiece of clearness and he carefully gives his reasons with the directness of a great legal mind.

The agitation of the Canteen question prompted the Secretary of War to send a circular letter to the commanding officer of every troop, battery, company and regiment, and under date of May 2, 1899, a similar letter to over five hundred of the oldest non-commissioned officers.

Following is a copy of the letter:

"HEADQUARTERS OF THE ARMY.
"ADJUTANT-GENERAL'S OFFICE,
"WASHINGTON, May 2d, 1899.

"SIR: The recent legislation (Section 17 of the Act approved March 2, 1899) in the matter of the sale of liquors by Post Exchange and the interpretation thereof by the Attorney-General (General Orders No. 69, 1899), together with what cannot be regarded as other than an abuse of the privileges accorded by the Exchange Regulations by certain undisciplined organizations during the recent war with Spain, have caused considerable criticism of the Exchange feature of the Army administration.

"With a view to a proper understanding of the situation the Secretary of War desires that commanding officers of every troop, battery, company and regiment in your command be called upon for a report based upon his experience and observation as regards the benefit or injury to the Army in point of temperance, morality and discipline as a result of the Exchange system and particularly as to the sale of beer.

"It has been publicly asserted by the opponents of the Exchange system that officers of the Army are restrained from expressing their true opinion on the subject by reason of the belief that the War Department has determined to maintain the Exchange in spite of opposition. The Secretary desires that such an impression be at once dispelled. In these reports, so long as they do not violate good taste and official decorum, the utmost latitude of opinion is invited in order that the Secretary may be in a position to place before Congress at the next session a correct report of the merits and defects of the Exchange system as seen by those best qualified to judge.

"In order that the replies to these inquiries may be as uniform as possible they will be made upon the accompanying form, a supply of which has been sent you under separate cover for distribution.

"H. C. Corbin,
"Adjutant-General."

To the question "So far as your observation has gone, have desertions increased or lessened since its introduction?" 345 commissioned officers and 394 non-commissioned officers (739) have replied that desertions have decreased; 4 commissioned officers and 2 non-commissioned officers (6) that they have increased; 31 commissioned officers and 18 non-commissioned officers (49) that its effect on desertions is doubtful; 79 commissioned officers and 37 non-commissioned officers (116) that it has had no effect and 123 commissioned officers and 32 non-commissioned officers (155) that they are unable to state.

To the question "Has drunkenness increased or lessened since the introduction of the Canteen feature of the exchange system?" 480 commissioned officers and 429 non-commissioned officers (909) have replied that it has decreased; 9 commissioned officers and 11 non-commissioned officers (20) that it has increased; 16 commissioned officers and 17 non-commissioned officers (33) that there is no difference and 77 commissioned officers and 26 non-commissioned officers (103) that they do not know.

To the question "In your opinion does the opportunity to procure beer at the Post or in camp have any effect upon the efforts of enlisted men to procure intoxicants outside?" 551 commissioned officers and 18 non-commissioned officers cers (980) have replied that it lessens such efforts; 6 commissioned officers and 5 non-commissioned officers (11) that it increases; 18 commissioned officers and 43 non-commissioned officers (61) that it does not have any effect and 7 commissioned officers and 6 non-commissioned officers (13) that they do not know.

To the question "What in your opinion would be the effect of an absolute prohibition of the sale of beer in the Army?" and to the question "Are you in favor of such prohibition or are you in favor of the Exchange as conducted at present and with a view to its continual improvement along the same lines?" 517 commissioned officers and 464 non-commissioned officers (981) have replied in favor of the Canteen; 17 commissioned officers and 19 non-commissioned officers (36) in favor of absolute prohibition and 3 commissioned officers doubtful. These latter questions contain the gist of the inquiry.

On February 20, 1900, Mr. Bowersock, of Kansas, introduced the following bill which was placed in the hands of the Commitee on Military Affairs for a report:

A Bill

To prevent the selling of, or dealing in, beer, wine or any intoxicating drinks in any Post Exchange or Canteen or transport or upon any premises used for military purposes by the United States.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, that the sale of or dealing in beer, wine, or any intoxicating drinks as a beverage by any person in any post exchange, or canteen, or transport, or upon any premises used for military purposes by the United States, is hereby prohibited.

Sec. 2. That the penalty of any violation of this Act shall be not less than one hundred dollars and not more than five hundred dollars for each offense.

The committee submitted the following report:

"The Committee on Military Affairs to whom was referred House Bill No. 8752 report the same back to the House with the recommendation that it do pass with the following amendments:

"Amend lines 5 and 6 by striking out the words 'for military purposes' and insert in lieu thereof the words 'or owned.'

"Amend the title by striking out the words 'for military purposes' and inserting the words 'or controlled.'

"The bill was referred to the War Department and a very *voluminous report* was returned to the Committee *against the passage of the bill,* but the Committee believes that in view of the *legislation of the last Congress* when it was intended to abolish the Canteen, but, on account of faulty language did not accomplish it, the *present bill should pass.* The expressions received from all parts of the United States go to the point that *even if the Canteen results in the decreased consumption of liquor by the Army, the United States Government should not in any sense be connected with the liquor traffic,* but let private parties conduct it under the laws of the different States.

"The Committee further believes that, if the Government should not permit the *selling of liquor in military reservations,* that it *should prohibit it in any other premises* owned or controlled by the Government of the United States and with the amendments suggested in the report that the bill do pass."

At a casual glance from those unfamiliar with the subject the report appears very consistent, but upon close scrutiny by any one acquainted with the facts it presents a series of inconsistencies. In order to comprehend more clearly these inconsistencies I would call attention to the words which are in italics.

From the first sentence we are led to believe that the Fifty-sixth Congress was endeavoring to blindly follow the lead of the Fifty-fifth Congress, and, despite the greater facilities for judging and in the face of a "very voluminous report against the passage of the bill," the Committee recommended its adoption.

We judge from the second statement that though drunkenness, alcoholism, desertions, and indirectly certain diseases are lessened, yet the Government should do nothing toward relieving this distressing state of affair. The Government is in no sense in the "liquor traffic," nor does it do more than inspect and control the Canteen in *practically* the same way as revenue officers regulate the sale of liquor throughout the United States.

The *soldiers* who have the rights of citizens *incur the expense* and they reap the benefit morally, physically, and financially. It seems hardly consistent, as the third paragraph states, to hold that the same rule governing military reservations should govern soldiers. They have certain rights of private citizens and *by virtue* of their *own volition* are serving as *protectors* of the *Government* instead, as are the Indians on some of our reservations, awaiting a favorable opportunity to give trouble to Uncle Sam.

It is a curious, but no less significant fact, that in all the discussion and in the report of the hearings before Congress, both in the House and Senate, there is given the direct testimony of only a single medical officer (Dr. Munson) and only one or two others are quoted. It seems a piece of great negligence to thus ignore the evidence of men who by the very nature of their profession are in a position to elucidate the subject and whose testimony should have greatest weight in passing on this momentous question.

The Association of Military Surgeons at their tenth annual meeting (St. Paul, May 30-June 1, 1901) after hearing and discussing Major Seaman's masterly article, entitled "Observations in China and the Tropics on the Army Ration and the Post Exchange or Canteen," unanimously passed the following resolution:

"*Whereas,* The Association of Military Surgeons of the United States now in session at St. Paul recognizes that the abolition of the Army Post Exchange or Canteen has resulted, and must inevitably result, in an increase of intemperance, insubordination, discontent, desertion and disease in the army, therefore be it

"*Resolved,* That this body deplores the action of Congress in abolishing the said Post Exchange or Canteen and in the interest of sanitation, morality, and discipline recommends its reestablishment at the earliest possible date."

I wish that every one who has not read Major Seaman's article and the discussion following would do so and thereby receive great enlightenment on so important a question.

I quote from some of the gentlemen who discussed this paper in order that we might reach a more thorough understanding of the matter. Colonel W. W. Grant of Colorado: "I hope everybody will discuss this paper. Congressmen do not expect to receive as much support from medical men as they do from others. If medical men would agitate this matter, if they were determined

and united in their demands on their Congressmen, they could accomplish for themselves, the welfare of the country and the sanitary conditions of the Army much more than they have yet accomplished. I do not think it worth while to say that women should not take an interest in this matter. They have the welfare of the Army and the best citizenship at heart. I think the underlying principles of the W. C. T. U. are based on the very best motives.

"I do believe if that organization is approached properly, and there is no organization in the country that public men and women respect more, they can be convinced that a mistake has been made; and that by united action we can show public men and public officials that we have influence."

Colonel R. H. Reed, of Wyoming: "It is unfortunate that we have a class of people in this country who are theorists. The class represented by the W. C. T. U. are doing a good work in their sphere, but they have no business to meddle with things that do not belong to them; they have gotten out of their sphere and have meddled in the laws of the United States in doing so."

Brigadier-General F. W. Byers, of Wisconsin: "The good women meant to do some good, but they went after it in the wrong way, and I think however much a Congressman may want to do his duty he usually counts the votes behind every measure that comes up. I do not like politics in the Army, I do not like politics in anything military, but there is politics in this, and we have got to give the authorities at Washington to understand that we have votes behind us as well as the W. C. T. U."

Lieutenant-Colonel J. D. Griffith, of Missouri: "If this Association can only convince Congress that it has taken a wrong step in that direction, it means everything to our Army—not only to the regular Army but to the volunteer, and let me say right here that the volunteer in the United States to-day is the bulwark of the Government. When this thing comes to a test the Canteen will come again. It is our duty to bring it forward and we must have it. It is a necessity; it may be a necessary evil, but we have them all over the land. We must have the Canteen."

Major T. C. Clark, of Minnesota: "Now I would be the last person in the world to question the motive of the women of the W. C. T. U. We all know that the instinct of women is always on the side of right. We may question her logic; we may accuse her of jumping at conclusions; we may question her wisdom as a legislator, but we must always give her credit for having a high motive and a pure instinct in combating that which she thinks is wrong. Consequently any action we may take here should be dignified, and we should try to make it as effective in that way as possible and I think the action of this association as embodied in this resolution, forwarded to members of Congress and spread broadcast throughout the country cannot fail to have its effect. The opinion of a body of medical men directly interested in this question should appeal to every thinking person, and if there are any members who hold views contrary to this resolution I hope they will speak them, because to my mind the sentiment of this Association should be unanimous and it ought to go a long way."

Major Geo. Halley, of Missouri: "I think the greatest mistake made has been the advocacy of total abstinence by legislation; that stand has been a mistaken one, and it is a mistake, not with reference to the temperance question alone, but with reference to a very large amount of effort that is made to place on the statute books laws to make morals. They may be right enough, I have no reason to doubt the wisdom of some of them, but on this particular question, dealing with temperance, it is unwise, it is fatal; it is absolutely impossible to stop men drinking. They have got into that habit and the best that can be done is to try to regulate it."

Major Allen A. Wesley, of Illinois: "I desire to state that the opinion of the medical officers of the United States Army is unanimous on this question, that is, if the press reports of Chicago are correct. The press is the educator of the people, and if the press does right and says that this Association demands the repeal of this law, Congress will take notice of it. I think, as has been stated, that we can also enlist on our side the W. C. T. U., and we can do that through the press and individually."

Lieutenant-Colonel Jno. Van R. Hoff, of the United States Army: "There is no question that the Post Exchange has its value. Its value is apparent to us; we know what it means; we know how good it is for our soldiers; we know how they promise temperance—and I distinguish between temperance and teetotalism. We all know that the soldier is just the same as the citizen, except that he wears a uniform. He has the same tastes, the same inclination, the same pulse under the blue as he has in the performance of his daily vocations as a citizen."

Brigadier-General George Cook, of New Hampshire: "I am in favor of the resolution as submitted by Maj. Seaman and I am also in favor of sending it to every Congressman and to every association of the W. C. T. U., whom I believe we should deal with kindly and generously and not call anything they have done by a harder term than to say they were misguided; then we can accomplish something."

It would be undignified and dishonorable to accuse the men above quoted as having any but the best motives at heart and no one can truthfully say that they are influenced by any ulterior designs. These men are medical officers with large experience and whose positions are such as to relieve them from the attack of personalities.

When the American Medical Association met in St. Paul (1901) the resolutions passed by the Association of Military Surgeons were presented before that body and referred to the Committee on National Legislation, whose report as here given was adopted on motion of Dr. Lewis of Chicago.

"Your Committee on National Legislation, to whom was referred the following resolutions from the National Association of Military Surgeons, presented to your honorable body by Major Louis L. Seaman, U. S. V.:

"*Resolved,* That this body deplores the action of Congress in abolishing the Army Post Exchange or Canteen, and, in the interest of discipline, morality, and sanitation, recommends its re-establishment at the earliest possible date.

"We have carefully considered the resolution proposed and declare it to be wise, proper, and of importance to every citizen of this republic.

"The resolution is the outgrowth of careful study and observation by the medical department of the United States Army, it is concurred in by the commanding officers at the several posts, and is intended to correct serious abuses under the present law which result in drunkenness, desertion, insubordination, dishonorable discharge, crime, poverty, appalling increase in venereal disease, and invalidism among the soldiers of the United States Army.

"We find that the experience of foreign governments coincides with that of the National Association of Military Surgeons in the necessity for the Army Post Exchange or Canteen.

"We recommend that the American Medical Association adopt the resolution proposed and that you petition the Congress of the United States to repeal, at the earliest moment, the objectionable law which prohibits the Army Post Exchange.

"Respectfully submitted,
"H. L. E. Johnson,
"Chairman Committee on National Legislation."

The American Medical Association has been accused of passing the resolution in an unparliamentary manner, the accusation being that the "ayes were called for, but not the noes."

In order to find out the truth of the statement I wrote to Dr. John A. Wyeth, President of the Association, and received the following letter:

"New York, September 16, 1901.

"Dear Doctor: I have your letter of September 13th. I have not seen the controversy in the Medical News. I was present at the meeting when the question of the Canteen was voted upon at St. Paul. It is my recollection that a very decided majority of the members present voted in favor of the result, and that when it was declared carried by the President it was fairly carried. Under the circumstances (I have to preside at the next meeting when the question is to be brought up), I scarcely think it would be appropriate for me to express an opinion, but will leave the matter in abeyance until I see you at the Saratoga meeting next June. I sincerely hope you may come, and that what I have written may be satisfactory to you for the purpose you have in view.

"Sincerely yours,
"John A. Wyeth."

I wrote the Surgeon-General as to his views of the Canteen and he kindly answered in the following manner:

"Washington, Oct. 12, 1901.

"Dear Sir: In reply to your communication of September 12th, I am directed by the Surgeon-General to send you the enclosed extract from his annual report for the year ended June 30, 1901, shortly to be published.

"The Surgeon-General has watched the progress in the decline of the prevalence of alcoholism with much satisfaction, and reported on it in each of his reports. I send you a copy of the report for 1896 in which on pages 84-88 and in Tables XII. and XVI. you will see the manner in which this record has been kept.

"Very respectfully,
"C. Smart,
"Assistant Surgeon-General, U. S. Army."

[Extract.]

"The steady decrease of late years in the admissions for alcoholism among the men of the regular army is a matter for congratulation. Military officers may be said to be unanimous in their opinion that this was mainly the result of the establishment of the Post Exchange or Canteen at military posts. The following shows this gradual improvement. Mean annual admission rate of the decade ending with 1889, 56.68 per thousand of strength. Admission rate for 1889, 41.44; for 1890, 40.73; for 1891, 40.01; for 1892, 37.23; for 1893, 33.97; for 1894, 30.94; for 1895, 30.11; for 1896, 29.06 and for 1897, 27.86. In 1898 the altered conditions consequent on the Spanish-American war prevented further comparisons. There is less drunkenness among troops in active service than in a command doing garrison duty in a time of peace."

Major James Evelyn Pilcher, Brigade Surgeon, U. S. V., Capt. (Retired), U. S A., at my request to furnish me with a copy of the *Journal of Military Surgeons* and to give me his views on the Canteen sent me the following letter:

"Carlisle, Penn., October 23, 1901.

"Dear Doctor: I will have pleasure in sending you a copy of the next number of the *Journal,* containing Major Seaman's article and the discussion upon it.

"So far as my personal opinions on the subject are concerned, I have no objection to your using my name if you desire, but I fancy it would hardly be worth while, as my opinion is simply that of the vast majority of medical officers who have had much experience with troops, viz., that while by no means free from evil qualities, the benefit to the men and the service enormously surpasses the disadvantages of the Canteen.

"Trusting that your article will be powerfully effective in propagating a correct view of the subject, I remain,

"Very sincerely yours,
"James Evelyn Pilcher."

Lieutenant-General Miles, in his latest report to the Secretary of War, in speaking of the prohibition of the sale of intoxicating beverages in the Canteen, says, "It is believed that no injury has resulted thereby and that the law has in the main been beneficial."

Such a statement from the Commanding General of the Army must have some weight, but consideration must also be given to the opinions of the Inspectors-General in their report which accompanies that of General Miles.

Colonel Burton (Cuba) says, "The officers generally complain that the elimination of beer from the Exchange has worked a hardship on the soldiers and has been detrimental to good order and military discipline."

Lieutenant-Colonel Reade (Dakota) says, "It is the consensus of opinion that the Exchange, with the Canteen feature, promotes the morals, temperance, discipline, and health of the men. Further, that in the interest of effective services and morality the Canteen should be reëstablished as a section of the post Exchange. It is better for men to drink beer on a military reservation, where they can be cared for, than to drink alcoholic liquor off of it. The recommendation previously made by me is renewed—that, whenever practicable, post or regimental chaplains be placed in charge of the Post Exchange."
